Although Petranka and Kennedy (1999, *op. cit*.) suggested diverse feeding strategies for generalized tadpoles, there is still a prevailing paradigm of pond tadpoles as obligate omnivorous suspension feeders. Oophagy on conspecifics greatly complicates current ecological theory and models by expanding the roles of tadpoles in temporary pond communities, the guild of predators faced by maturing conspecifics, and the strategic challenges faced by females selecting breeding sites.

I thank T. G. Forrest for photographs, J. W. Petranka for positive identification of the tadpoles, and R. B. Cocroft, T. G. Forrest, G. Hoebel, and J. W. Petranka for helpful comments.

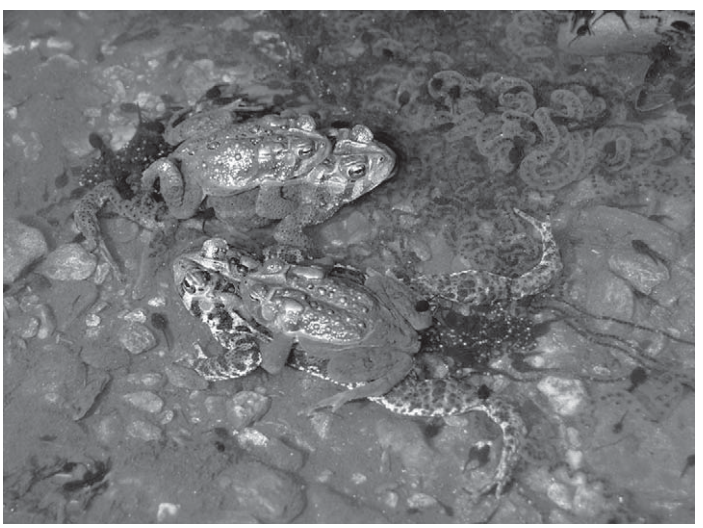

FIG. 1. *Anaxyrus americanus* tadpoles feeding on egg masses from ovipositing female conspecifics in a shallow pool at the confluence of Big and Fletcher creeks (Henderson County, North Carolina, USA). Photo taken 21 May 2006 by T. G. Forrest.

BUFO BOREAS BOREAS (Boreal Toad). **PREDATION**. Olson (1989. Copeia 1989:391–397) reported Raven (*Corvus corax*) predation on adult *Bufo boreas* at three breeding aggregations in the central Cascade Mountains of Oregon (USA). However, carcass condition prevented Olson (1989, *op. cit.*) from identifying the gender of predated animals. Here, we provide additional observations of *B. boreas* predation attributable to *C. corax* from another population in the Oregon Cascades. In these, we were able to distinguish the gender of predated toads, providing novel insight into this phenomenon.

MPH and RFP made these observations at Horse Lake, Douglas County, Oregon (43.1266°N, 122.1533°W; datum WGS84, elev. 1586 m) in 2007. However, MPH had also collected observations at this site over four additional years since 1997. The latter observations were always made over a 2–3 day period during snowmelt (May) when *B. boreas* breeding was at its peak. Horse Lake is a small (1.5 ha) lake underlain by a pumice-dominated volcanic lithology and surrounded by mature Lodgepole Pine (*Pinus contorta*) with a thin understory. It has two subequal lobes positioned northwest–southeast that are connected at high water; though maximum depth is ~1.5 m, 80% of the lake is <1 m deep.

During an extensive visual encounter survey of Horse Lake and vicinity between 1145 and 1540 h on 11 May 2007, we found the remains of 8 *B. boreas*, 7 at Horse Lake and an 8th individual in a small (0.1 ha) sedge-filled pond ca. 150 m south of Horse Lake. In each case, remains included a near-complete skin. Based on the sizes of 39 live adult toads measured at Horse Lake (males: N = 37, mean = 96.9 mm SVL, SD = 6.2; females: N = 2, mean = 113 mm SVL, SD = 6.2), all belonged to adults ca. 90–110 mm SVL. These skins were remarkable in that except for one in which a forearm bone and a little flesh remained, all had been pulled inside out, often down to the digits, and were thoroughly cleaned of flesh and bone. All skins seemed fresh; they were moist, pliable, and displayed coloration we could not distinguish in quality from that of living adult toads. Each skin was also notable in that the severed margin was always on the ventral side; the skin across the entire back and sides (including the parotoid glands) was always intact, making it easy to observe the toad's original dorsal color pattern by laying the skin flat. We found 6 of the 8 skins on downed Lodgepole Pine logs bordering Horse Lake; the remaining two were in water. In addition to the skins, fragments of toad ovaries were found within 1 m of five of the six skins. Notably, we saw no well-developed eggs in any discarded ovaries. As individual toad skins were scattered (all were >5 m apart), discarded ovaries helped determine gender. However, presence (or absence) of nuptial pads on toad skins (easily viewed on fresh skins by inverting the skin of the digits on an anterior limb) was the definitive criterion for gender determination. In every case, at least one anterior limb had some intact digits. Male Western Toads at Oregon Cascade sites where we have collected data develop nuptial pads on the dorsolateral surface of digits 1, 2, and 3 on the anterior limbs (MPH, unpubl. data), so only one of these digits needed to be intact for gender determination. Color pattern of the dorsal skin also helped confirm

gender since females tend to have a more complex or blotched pattern than the more uniformly colored males (Blair 1963. Evolution 17:1–16; Schueler 1982. Can. Field Nat. 96:329–332).

During our 2007 survey, we also found toad egg strings that we estimated as representing the complement of at least 29 egg masses (i.e., we counted at least 58 separate egg strings; each female deposits one pair of separate strings: see Kagarise Sherman 1980. Ph.D. dissert., University of Michigan, Ann Arbor, Michigan. 394 pp.), and observed 15 additional adult toads that were not measured. Because each female is assumed to lay eggs once per breeding season (Kagarise Sherman 1980, *op. cit.*) and the two living females we found appeared gravid, we observed evidence of at least 91 adult toads during our survey, 9% (N = 8) of which were dead. This would overestimate mortality if live adults contributing to this aggregation were missed, or underestimate it if we missed dead adults; both are possible.

We attributed the dead toads to *C. corax* predation because we observed a Raven fly away from the *B. boreas* breeding aggregation as we approached it, and the pattern of predation was nearly identical to that which Olson (1989, *op. cit.*) described. However, we cannot unequivocally exclude other predators. We observed at least two pairs of Gray Jays (*Perisoreus canadensis*) during our 2007 survey, and MPH has recorded Clark's Nutcrackers (*Nucifraga columbiana*), a known toad predator (Mulder et al. 1978. Condor 80:449–451; Kagarise Sherman and Morton 1993. J. Herpetol. 27:186–198), on previous visits. However, in five years of visits to this breeding aggregation, this is the first time we recorded predation on adult toads. Two further aspects merit comment. Given the high visibility of nearly constantly moving male *B. boreas* in the breeding aggregation, we were surprised to find that most dead adults we encountered were female. This is especially true given our general experience that female toads are far less conspicuous (to the human eye) in breeding aggregations, a pattern consistent with other observations (Olson et al. 1986. Oecologia 70:351–356; Kagarise Sherman 1980. *op. cit.*). Lack of developed eggs in discarded ovaries also raises questions regarding the female toads that were prey. These could represent either post-breeding or non-gravid females, but given apparent female-biased predation, such females may exhibit unrecognized vulnerability to predators.

Work was done under an Oregon Department of Fish and Wildlife scientific handling permit 031-07 to C. Rombough, under which MPH was a permitee; conditions of this permit require adherence to the guidelines for use of live amphibians and reptiles in the field (Beaupre et al. 2004. Guidelines for use of live amphibians and reptiles in field and laboratory research, Second edition. Herpetological Animal Care and Use Committee of the American Society of Ichthyologists and Herpetologists). We thank C. Rombough and D. Olson for valuable comments. This is contribution No. 15 of the Forests and Fish Section of the Washington Department of Fish and Wildlife Habitat Program Science Division.

Submitted by **MARC PHILIP HAYES**, Washington Department of Fish and Wildlife, Habitat Program, 600 Capitol Way North, Olympia, Washington 98501, USA (e-mail: hayesmph@dfw.wa.gov); and **ROBERT FRANCIS PRICE**, 333 Thomas Street NW, Olympia, Washington 98502, USA (e-mail: robpri@care2.com).

BUFO BUFO (Commond Toad). **PARASITISM**. The distribution of *Bufo bufo* covers the whole of Europe, northeastern Africa, and western Asia (Nöllert and Nöllert 1992. Los Anfibios de Europa. Omega Editions. 399 pp.). It breeds mainly in permanent water (Lizana 1997. *In* Pleguezuelos (ed.), Distribución y Biogeografía de los Anfibios y Reptiles de España, pp. 152–154. Asociación Herpetológica Española, Universidad de Granada, Granada), where it may be parasitized by different species of leech (Hoffmann 1960. Notules Hirundinologiques. Archieves de la Section des Sciences Naturalles, Physiques et Mathematiques de L´Intitut Grand-Ducla de Luxembourg [new series] 27:285–291; Fontaneto et al. 1998. *In* Miaud and Guyétant [eds.], Current Studies in Herpetology, pp. 121–124. Societas Europaea Herpetologica, Le bourget du lac, France). Parasitism of adult *Bufo bufo* by the leech *Hirudo medicinalis* has been reported in previous studies (Hoffmann 1960, *op. cit.*; Fontaneto et al. 1998, *op. cit.*), although its attack on other *B. bufo* developmental stages has not been described.

On 30 July 2007, a larval *B. bufo* (total length = 26 mm; Gosner Stage 37) (Gosner 1960. Herpetologica 16:183–190.) was found being parasitized by *H. medicinalis* in a permanent cistern located in Sierra Espuña Regional Park (Province of Murcia, southeastern Iberian Peninsula, 37.86873°N, 1.52032°W; European 1950 datum; 772 m elev.). The leech was attached to the back of the larva, which was forced to swim in a supine position (Fig. 1). Because both larva and the leech were preserved immediately after capture, the consequences of this parasitism on natural history traits, such as locomotion, feeding, and survival of the affected larva, could not be assessed.

We thank the Consejería de Desarrollo Sostenible y Ordenación del Territorio de la Región de Murcia for providing the corresponding permits.

BUFO MELANOSTICTUS (Spectacled Toad). **ARBOREAL BEHAVIOR**. *Bufo melanostictus* is a typical ground dwelling toad; based on its relatively short hind limbs. This species naturally occurs in the Himalayas, India, Indochina, Indo-Australian Archipelago, Malaysia, Myanmar, southern China (Nutphund 2001. Amphibians of Thailand. Amarin Printing and Publishing, Thailand.192 pp. [in Thai]) and Taiwan, including Orchid Island and Green Island (Lue et al. 2002. The Transition World—Guidebook of Amphibians and Reptiles of Taiwan. SWAN, Taipei. 350 pp. [in Chinese]; Yang 1998. A Field Guide to the Frogs and Toads of Taiwan. Taipei. Nature and Ecology Photographer's Society. 144 pp.).

At 0954 h on 03 Aug 2007, a sub-adult male *Bufo melanostictus* (47 mm SVL) was found 1.6 m above ground, on the trunk of a *Macaranga tanarius* that was growing at a 45º angle out of an embankment in a secondary forest in Santzepu, Sheishan District, Chiayi County (23.42666°N, 120.48583°E; WGS84; elev. 90 m). The habitat consisted of *Tetrastigma formosanum*, *Alocasia macrorrhiza*, *Alpinia zerumbet*, *Brachiaria mutica*, *Christella acuminata*, *Cinnamomum camphora*, *Clerodendrum paniculatum*, *Costus speciosus*, *Dimocarpus longans*, *Ichnanthus vicinus*, *Lantana camara*, *Lygodium japonicum*, *Macaranga denticulata*, *Machilus thunbergii*, *Maesa perlaria* var. *formosana*, *Mangifera indica*, *Mikania micrantha*, *Miscanthus sinensis*, *Morus australis*, *Passiflora foetida* var. *hispida*, *Smilax ocreata*, and *Stephania japonica*. The canopy cover, created by the crowns of *C. camphora* and *M. denticulata*, was 80%.

No possible prey or refuge was observed on the trunk, so it is not clear why the *B. melanostictus*, which is a nocturnal terrestrial species, was in an arboreal location during the day. We believe the arboreal behavior of the toad could relate to its thermal requirements. The highest air temperature (36.3ºC) for Chiayi County for 2007 was recorded on the same day, and was 8.4ºC higher than the mean air temperature (27.9ºC) of August (Central Weather Bureau. 2007. Monthly Report on Climate System. Ministry of Transportation and Communications, Taipei. [in Chinese]). Arboreal relocation probably offered better air circulation and reduced thermal stress for the toad. This appears to be the first description of arboreal behavior in *B. melanostictus* from Taiwan.

CRAUGASTOR BRANSFORDII (Bransford's Rain Frog). **REPRODUCTION AND NEST SITE.** The genus *Craugastor* contains 111 currently recognized species of Neotropical direct-developing brachycephalid frogs (Frost 2007. Amphibian Species of the World. Vers. 5.1. http://research.amnh.org/herpetology/amphibia/index.php). While all species in this genus are presumed to exhibit direct development of eggs and many species exhibit parental care, few reports of reproduction have been documented within the genus (Townsend 1996. *In* Powell and Henderson [eds.], Contributions to West Indian Herpetology, a Tribute to Albert Schwartz, pp. 229–239. SSAR Conrib. Herpetol. Vol. 12. Ithaca, New York). We are aware of no documentation of reproduction for *C. bransfordii*, nor for any other member of the *bransfordii* species group. Herein, we report the first description of reproduction in *C. bransfordii* from primary forest within La Selva Biological Station (10.42°N, 84.00°W; WGS84, ca. 60 m elev), Heredia Province, northeastern Costa Rica.

On 23 Aug 2007, we encountered a female *C. bransfordii* (22.4 mm SUL) perched on top of a clutch of eggs at ca 1300 h. The nest site was on bare soil from which leaf litter had been removed, between the stilt roots at the base of a small (10 cm diam) palm. We observed the female rotating the longitudinal axis of her body over the clutch, keeping her mid-venter positioned directly over the center of the clutch as her head and legs rotated around the periphery of the nest cavity. She was observed performing this unusual behavior intermittently for approximately one hour. We returned at ca 1900 h on the same day to conduct a closer inspection of the nest site. The female was still present in the same location, but was perched on bare soil, and no eggs were visible at that time. We removed the female and located the clutch under ca 5 mm of soil. The egg mass measured ca 15 × 14 × 12 mm, and consisted of ten eggs. Four individual eggs from the clutch measured 3.7, 3.9, 4.1, and 4.4 mm in diameter, but the other six eggs were not measured. Using a staging table developed for another species of brachycephalid frog (Townsend and Stewart. Copeia 1985:423–436), we estimated the developmental stage of these eggs to be stage 1—the yolks were featureless and cream-colored and were surrounded by a thin clear covering. While the staging table we used is species-specific and was developed for *Pristimantis coqui*, *Pristimantis* and *Craugastor* are presumed to share a common evolutionary origin of direct-development, and Townsend and Stewart (1985, *op. cit.*) provide the only staging table for direct-developing embryos of which we are aware. We returned to the nest site on 24 Aug 2007 at ca 1130 h, and on several occasions thereafter, but did not detect the female within a 3 m radius of the nest site despite a careful examination of the surrounding area. We checked the status of the nest on 3 Sept 2007 by carefully removing the soil covering the nest, and the clutch appeared intact. We returned to the nest site once again on 20 Sept 2007. At this time, there were no eggs present in the nest site, nor was there any evidence of disturbance surrounding the nest cavity.

Within the genus *Craugastor*, nests are often constructed in shallow depressions excavated by the parent, but we are not aware of burial of eggs by any species in this genus. We presume that the unusual rotating behavior we observed was a behavior of the female to draw soil from the edges of the nest depression to cover the eggs. While many species of *Craugastor* are characterized by parental care by either the male or female parent (Townsend, *op. cit.*), we detected nest attendance by the female only for a short time after the eggs were presumably laid. However, because we disturbed the female parent, we cannot objectively evaluate whether further

parental behaviors would have occurred. Finally, we are also unable to determine whether the nest in the field failed or hatched, or whether our disturbance of the nest played any significant role in its fate.

Submitted by **STEVEN M. WHITFIELD** (e-mail: steven.whitfield@fiu.edu), and **KELSEY REIDER** (e-mail: reider.12@gmail.com), Florida International University, Department of Biological Sciences, U.P. Campus, OE 167, Miami, Florida 33199, USA.

ELEUTHERODACTYLUS* cf. *PARVUS (Girard's Robber Frog). **PREDATION.** Predation on anuran amphibians by spiders has been reported many times in the literature and appears to be a common phenomenon in the neotropics (Menin et al. 2005. Phyllomedusa 4:39–47; Costa et al. 2006. Herpetol. Rev. 37:337–338; Pazin 2006. Herpetol. Rev. 37:336). Herein, we present another case of predation of an anuran by a spider, adding another neotropical frog species to the list of amphibians known to be preyed upon by spiders.

On 18 Aug 2005, at the Reserva Ecológica de Rio das Pedras (22.98333°S, 44.1°W; 370 m elev, SAD 69), municipality of Mangaratiba, State of Rio de Janeiro, Brazil, one of us (JALP) captured a spider, *Oligoctenus medius* (Ctenidae) with a live frog, *Eleutherodactylus* cf. *parvus*, being held between its chelicerae. The spider and its prey were found on the leaf litter at 1910 h. The frog, which was being held by the abdominal region in the spider's chelicerae, was released when the spider was picked up by the observer, and remained alive for about 15 h afterwards, until being euthanized. The spider (female; body length = 31 mm; mass = 2.7 g) was later deposited at the arachnological collection of the Museu Nacional, Rio de Janeiro (MNRJ 03085), whereas the frog (unsexed; SVL = 15.4 mm; mass = 0.37 g) was deposited in the herpetological collection (MNRJ 40177).

Members of the families Ctenidae, Pisauridae, Sparassidae, Lycosidae, and Theraphosidae (especially the first two) appear to be the most common arachnid predators of neotropical anurans (Brescovit et al. 2004. *In* Marques and Duleba [eds.], Estação Ecológica Juréia-Itatins. Ambiente Físico, Flora e Fauna, pp. 198–221. Holos Editora, Ribeirão Preto; Menin et al. 2005, *op. cit.*; Costa et al. 2006, *op. cit.*), and the present report agrees with this trend. Menin et al. 2005. (*op. cit.*) observed a trend for spiders preying on frogs in the neotropics to be about the same size or slightly smaller than its prey, but our report does not concur with the apparent trend, as the spider was considerably larger than its anuran prey. Since the frog remained alive and apparently in good health after being released by the spider, it is possible that the spider had not yet injected it with venom by the time it was captured, as the venom of ctenid spiders is frequently quite potent and can cause paralysis and death in small vertebrates within a short time (Massary 1999. Herpetol. Rev. 30:167; Teixeira et al. 2003. Herpetol. Rev. 34:368–369; Menin et al. 2005, *op. cit.*).

We thank C. A. G. da Cruz and J. P. Pombal Jr. for identifying the frog and E. Winskonski for identifying the spider. Fieldwork at the Reserva Ecológica de Rio das Pedras was financed by the Critical Ecosystems Partnership Fund (CEPF).

HYLA ARBOREA (Tree Frog). **BLOWFLY PARASITISM**. *Lucilia*-fly parasitism on *Bufo bufo* in Europe is well documented and most often concerns the blowfly *Lucilia bufonivora* which seems to favor *B. bufo*. Incidentally, infections by maggots in the nostrils of other amphibians, including *B. calamita, B. viridis, Alytes obstetricans, Pelobates fuscus, Rana arvalis, R. esculenta, R. temporaria*, and *Salamandra salamandra* are reported (Koskela et al. 1974. Ann. Zool. Fennici. 11:105–106; Garanin and Shaldybin 1976. Parazitologiia 10:286–288; Krous 2007. J. Nat. Hist. 41:1863–1874). There is one report on the presence of *Lucilia* eggs on *Hyla arborea* in Switzerland (Meisterhans and Heusser 1970. Mt. Schweiz. ent. Ges. 43:41–44). This frog was kept in captivity to study the development of the *Lucilia* infection. After Day 3 the eggs were gone, and on Day 10 the *H. arborea* was healthy with no sign of *Lucilia* maggots in the nostrils or other forms of myiasis. The authors suggested the eggs were less strongly attached to the frogs' skin, as compared to earlier observations on bufonids.

On 13 August 2007, an infected *H. arborea* (Fig. 1) was found in De Doort, middle part of Limburg, The Netherlands. This is the first documented report of a *Lucilia* infection on *H. arborea*. The frog or maggots were not collected and thus the species of *Lucilia* remains uncertain.

LEPTOBRACHIUM SMITHII (Smith's Litter Frog). **DEFENSE AND PIGMENTATION**. The megophrid frog, *Leptobrachium smithi* has been described from Thailand (Matsui et al. 1999. Japan J. Herpetol. 18:19–29), Myanmar (Das and Chanda 2004. Asiatic Herpetol. Res. 10:245–246), India (Sengupta et al. 2001. J. Bombay Nat. Hist. Soc. 98[2]:289–291), and Laos (Stuart 2005. Herpetol. Rev. 36:473–479). Chuaynkern et al. 2007 (Herpetol. Rev. 38:323–324) noted its distribution in Bangladesh, citing Asmat et al. 2003. (Univ. J. Zool. 22:141–143); however, Asmat et al. 2003, *op. cit*.) did not actually report its occurrence in Bangladesh.

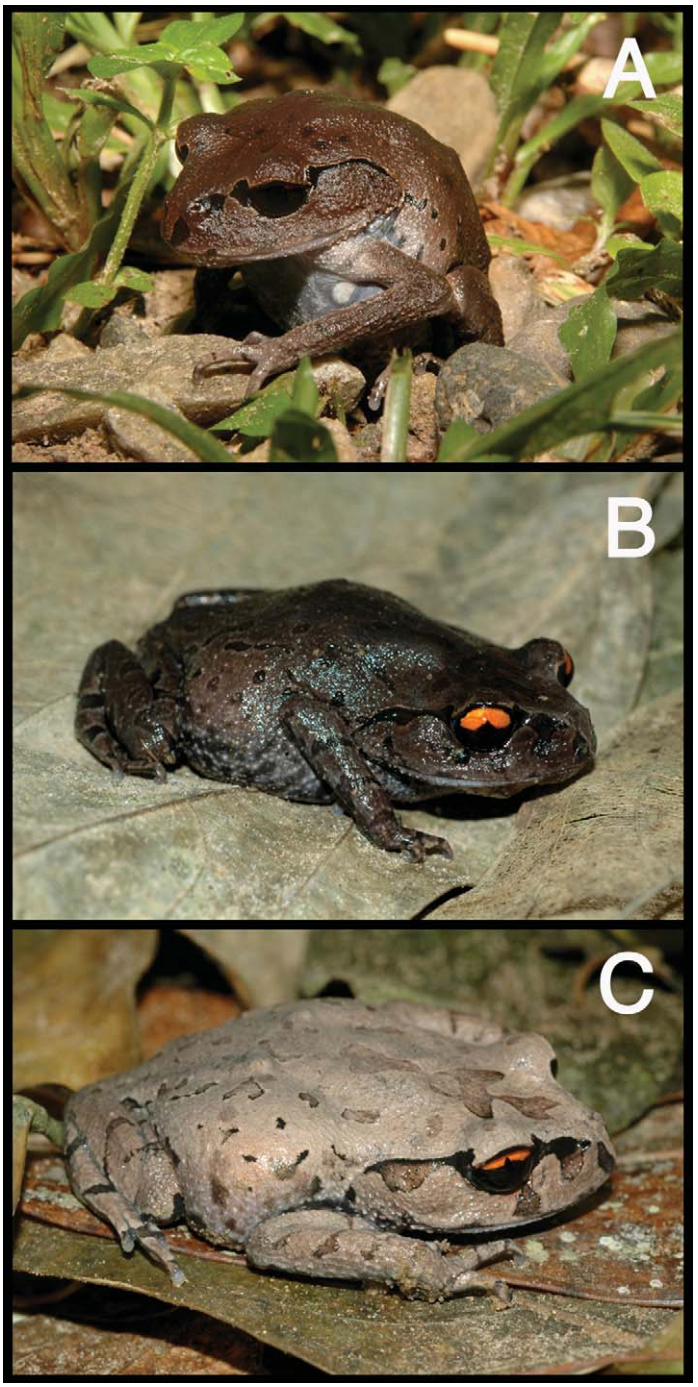

FIG. 1. A) *Leptobrachium smithi*, with its head arched (ca. 90°) towards the vent. B) Adult *L. smithi* with the true color and distinct red-eye before being manipulated. C) The same *L. smithi* completely loses its color after being held in a plastic jar for 30 min.

Defensive behavior has been described in *L. smithi* but defending its body by arching its head towards the vent and by changing its color has not been previously reported.

On 27 June 2007, an adult *L. smithi* (Jahangirnagar University; JU 0058) was found stalking prey at about 2230 h on a rail-way line in the middle of a hilly evergreen forest of Lawachara National Park (24.316°N, 91.783°E; WGS84, 144–150 m elev.), Moulvibazar District of northeastern Bangladesh. When approached and disturbed with a strong camera flash, the frog arched its head towards the vent (ca. 90°) while pushing its body into the rocky ground and remaining motionless (Fig. 1A). Similar behavior has been described in *L. smithi* but with a head arched ca. 90° elevated in opposite direction (Chuaynkern et al. 2007, *op. cit*.) which reveals the capability of the species to bend its head both ways up to 180°. While carrying the frog in a plastic jar for less than an hour, its body color changed completely into a light-ash color (Fig. 1C) from its original dark color with contrasting orange and black eye (Fig. 1B). When the ash-colored frog was taken out of the jar, it remained motionless for several minutes and then tried to escape by moving backwards.

Fieldwork was supported by the Cleveland Metroparks Zoo and Rufford Small Grants Foundation. This work was conducted under the official permission of the Bangladesh Forest Department (CCF(wildlife)/2M-47/2006). I thank Gad Perry for guidance and Md. Kamal Hossain from Jahangirnagar University for accompanying me in the field.

***PROCERATOPHRYS* SP.** (NCN). **PREDATION.** The Cerrado species of the genus *Proceratophrys* belong to the *cristiceps* group, and are found in open grasslands and gallery forests (Reuber Brandão, pers. comm.). On 12 March 2002, four adult White-eared Puffbirds (*Nystalus chacuru*, Bucconidae) were captured in mist nets in a "campo cerrado" area at Fazenda Água Limpa, Distrito

FIG. 1. White-eared Puffbird captured in a mist net carrying a *Proceratophrys* sp.

Federal, Brazil. One was holding a *Proceratophrys* sp. in its beak (Fig. 1). The White-eared Puffbird digs in the ground or in banks to construct a gallery as an entrance for the nest chamber, and could have captured the frog in its diurnal retreat on the soil. It is a common Cerrado bird that is mostly insectivorous, although other food items including lizards and vegetable matter have been reported (Del Hoyo et al. 2002. Handbook of the Birds of the World. Cotingas to Pipits and Wagtails. Lynx Edicions, Barcelona). This is the first record of a White-eared Puffbird predating a frog.

Submitted by **MIEKO F. KANEGAE**, Laboratory of Ornithology, Dept. Ecology, São Paulo University, São Paulo, Brazil (e-mail: miekok@terra.com.br); and **THAÍS M. AGUILAR**, Biology Course, Instituto de Educação Superior de Manhuaçu, Minas Gerais, Brazil (e-mail: thais_maya@yahoo.com.br).

SCAPHIOPUS COUCHII (Couch's Spadefoot). **PREDATION**. Predation upon larval *Scaphiopus couchii* by vertebrate and invertebrate predators has been well documented (Duellman and Trueb 1986. Biology of Amphibians. McGraw–Hill, New York. 670 pp.). Predation upon adults is likely common as well, especially during active periods such as the breeding season. However, there are few comprehensive studies detailing predation upon adult *S. couchii*. On 3 Aug 2006 at ca. 2400 h during a trip through Bottomless Lake State Park (Chaves Co., Roswell, New Mexico, USA: 33.31583°N, 104.32307°W; WGS84) we found a single adult male *S. couchii* on a road being consumed by an adult Common Barn Owl (*Tyto alba*). The owl had pinned down the toad with one talon piercing the midsection and had already created a large wound on the toad's back using its beak. The owl immediately flew away when our vehicle headlights illuminated the area from ca. 10 m away. The toad was still alive when collected, but expired shortly thereafter. The specimen was deposited in the University of Texas at Arlington Amphibian and Reptile Diversity Research Center (UTA–A57962).

To our knowledge, this is the first documented instance of predation upon *Scaphiopus couchii* by an avian predator. Common Barn Owls prey heavily upon small mammals, but have been known to eat other prey, including frogs (del Hoyo et al. 1999. Handbook of Birds of the World: Volume 5: Barn-owls to Hummingbirds. Lynx Edicions, Barcelona). This observation suggests that Common Barn Owls living in arid regions may utilize *S. couchii*, or desert breeding anurans in general, as a seasonally abundant food resource. *Scaphiopus couchii* adults may be attractive prey items during the breeding season owing to their large numbers, increased activity, and conspicuous advertisement calls.

SCINAX FUSCOMARGINATUS (NCN). **PREDATION**. Batracophagy between adult anurans is not frequently documented. Cardoso and Sazima (1977 Ciência e Cultura 29:1130–1132) reported predation of *Chaunus granulosus* by *Leptodactylus labyrinthicus* in Parque Nacional de Sete Cidades, in state of Piauí, Brazil. Cannibalism of nests and tadpoles of other species has been reported by *Leptodactylus labyrinthicus* tadpoles (Silva et. al. 2005. J. Nat. Hist. 39:555–566). On 13 Dec 2006, at 1000 h (air temp. 21°C; water temp. 24°C) we observed an adult *Scinax fuscomarginatus* (20.5 mm SVL), being captured by a adult *Leptodactylus furnarius* (30.7 mm SVL). This observation occurred beside a pond, located in Botucatu (22.923°S, 48.458°W, 800 m elev, WGS84), State of São Paulo, Brazil. The pond was filled with water, the soil around the pond was sandy, and there were small grasses along the shoreline. The *S. fuscomarginatus* was captured by its posterior left leg as it walked close to the L. *furnarius* (Fig. 1). Both individuals were collected and deposited at the Departamento de Zoologia, Instituto de Biociências da UNESP-Botucatu (*S. fuscomarginatus* CCJJ 7816; *L. furnarius* CCJJ 7817).

FIG. 1. An adult *Scinax fuscomarginatus*, captured by a adult *Leptodactylus furnarius*.

TESTUDINES — TURTLES

CHELYDRA SERPENTINA SERPENTINA (Common Snapping Turtle). **NESTING BEHAVIOR AND SITE SELECTION.** On 31 May 2008, we observed a ca. 36 cm CL C*helydra serpentina serpentina* in unexpected nesting circumstances. Observations were made from 0908 to 1027 h on clear day with ambient temp ca 24°C. The nest site near Longmont, Colorado, USA (40.1599528°N, 105.1259861°W; WGS84) was 4.3 m from a seasonal ditch running north-south to connect two lakes, one on either side of a busy road. The intriguing aspect of the nest location was that it was immediately adjacent to a heavily traveled concrete sidewalk that bordered a road with a high volume of traffic. The frequent foot traffic on the sidewalk and virtually constant vehicle traffic on the adjacent road did not deter the turtle from the particular nest loca-

tion, even though virtually identical soils, gradients, and directional aspects were available equidistant from the ditch, but away from constant human activity. In fact, aside from the potential for nesting disruption, the particular nest location might hold incubation advantages. The position adjacent to the sidewalk might yield thermal advantages from radiant heat from the sidewalk, both above and below ground. The depth of the nest was ca. 15 cm, similar to the thickness of the sidewalk, and probably allowing the entire depth of the nest to be warmed by heat stored in the concrete. The nest was also on a west-facing side of the ditch, allowing it to receive maximal effect of solar radiation during the summer. Altitude is a limiting factor in Colorado for the range of C. *s. serpentina*, with the species only distributed below 1680 m elev. (Hammerson 1999. Amphibians and Reptiles in Colorado. 2nd ed. University Press of Colorado, Niwot). At 1518 m, the elevation of the nest site might be high enough such that any thermal advantages could be important.

Assuming the turtle lives in the pond on the same (south) side of the road as the nest, and can only use the ditch, which connects the ponds on the north and south sides of the road on a seasonal basis (spring only), then there are ca. 3–4 ha of open area for nest building. Unlike turtles that live in city parks where the body of water is often surrounded by sidewalks or bike paths, this turtle had >99% chance to choose a less traveled location to lay her eggs. Using the ditch to gain access to her nesting site provided many opportunities to exit the ditch anywhere along its ca 30 m length to lay her eggs in a non-traveled and secluded area. The ditch embankments are such that they would not inhibit her ability to climb out of the ditch at any location along the way.

At the time observations were initiated, ca. 20 eggs appeared to have already been deposited in the nest. Egg laying was completed at 0932 h. During the 24 min from initiation of observations, 15 additional eggs were added to the clutch already in the nest (average inter-egg interval: 1 min. 36 sec). By 1025 h (53 min after final egg was laid), the turtle had completed covering the nest to the extent it could not be distinguished from the neighboring ground. By 1027 h the turtle had re-entered the ditch.

Unfortunately, this nest was destroyed by a Raccoon (*Procyon lotor*) on 30 August 2008 (predator identification based on tracks and scat), so we were unable to determine if the nest would have produced viable hatchlings. The adjacent ditch, which is often dry by late summer, had been filled during an unusual heavy rain event, so it seems possible that hatchlings might have successfully dispersed if the nest had not been predated.

CLEMMYS GUTTATA (Spotted Turtle). **DISPLACEMENT.** *Clemmys guttata* utilizes a wide variety of shallow wetland habitats including streams, marshlands, and swamps (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, DC. 578 pp.). Juveniles of this species (≤ 6 cm carapace length) tend to be secretive and are observed less often than adults (Ernst 1976. J. Herpetol. 10:5–33). On 16 May 2008, I observed a juvenile *C. guttata* (carapace length 5 cm, with 3–4 annuli) swimming westward across the Patuxent River (38.7839222°N, 76.7093278°W) in Maryland. The river at this location is ca. 110–120 m wide, with a depth of 3 m. On the east side of the river, a 400-m wide freshwater tidal marshland dominated by Spatterdock (*Nuphar advena*) separates the main channel from the adjacent floodplain, where adult *C. guttata* are commonly sighted. The juvenile was captured while swimming close to the water's surface and was photographed for verification.

This unusual occurrence might be explained by a major flood that took place on 14 May 2008. A late northeastern storm caused the river's channel to expand significantly, with strong currents that deposited large amounts of debris along the banks. This turtle might have been displaced by the effects of the storm, and was possibly attempting to return to its place of origin. Other species of semi-aquatic and terrestrial turtles were also sighted adjacent to or swimming across the Patuxent River following the storm, suggesting that the displacement of turtles as a result of major weather events is not uncommon. Previous investigators have found that strong current velocity associated with floods might displace turtles from their home ranges (MacCulloch and Secoy 1983. J. Herpetol. 17:283–285; Moll and Legler 1971. Bull. Los Angeles Co. Mus. Nat. Hist. 11:1–102). Moll and Moll (2004. The Ecology, Exploitation, and Conservation of River Turtles. Oxford University Press, pp. 23–24) suggest that displacement as a result of flooding is more likely to affect juvenile age class individuals of semi-aquatic turtle species. Ernst (1968. Herpetologica 24:77–78) reported that of 25 adult *C. guttata* relocated a distance of 310 m from the original capture point, 14 were later recaptured within 27 m of their capture point, suggesting that this species might have some homing ability.

This observation was made while conducting research at the Jug Bay Wetlands Sanctuary in Lothian, Maryland. Chris Swarth, Sanctuary Director, assisted in identifying and measuring *C. guttata*, and provided additional local observational records of the species.

GLYPTEMYS INSCULPTA (Wood Turtle). **DIET.** North American Wood Turtles are omnivores that feed on a variety of sources, including green leaves, fruits, algae, moss, fungi, insects, slugs, snails, and earthworms (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington D.C. 578 pp.; Harding 1997. Amphibians and Reptiles of the Great Lakes Region. University of Michigan Press, Ann Arbor, Michigan. 378 pp.). Wood Turtles feed opportunistically, as the abundance and availability of food items changes seasonally, and are known to scavenge animal carcasses, including fish (Harding 1997, *op. cit.*; Farrell and Graham 1991. J. Herpetol. 25:1–9). As part of a population genetics study, we collected morphometric data and DNA samples from 47 *Graptemys insculpta* in Berkeley County, West Virginia during May 2008 and noted feeding events and food items when possible. Wood Turtle food sources in Berkeley County (listed in order of frequency of observation) included grasses,

green leaves, berries, moss, and a dried Scarlet Oak leaf (*Quercus coccinea*). On 21 May 2008, we noted evidence of ophiophagy in two adult female Wood Turtles from Berkeley County. At 1335 h, an adult female Wood Turtle (mass = 1050.0 g; carapace length = 189.59 mm) defecated a 27.2 x 19.7 mm section of intact, previously shed snake skin. The skin section was undigested, clearly a shed specimen, and appeared to be from a gartersnake (*Thamnophis* sp.). At 1501 h, another adult female (mass = 986.0 g; carapace length = 181.75 mm) defecated a 62.4 x 11.1 mm section of partially digested Ring-necked Snake (*Diadophis punctatus*) while cloacal temperature was being recorded. This specimen had intact skin and muscle, and several vertebrae and ribs emerging from one end. Snake material, including exuviae, has not been reported as a food item for *G. insculpta*.

Thamnophis and *Diadophis punctatus* are both abundant in Berkeley County, although all *D. punctatus* we observed were found well hidden under rocks and logs during daylight hours, when Wood Turtles typically forage. *Diadophis punctatus* is nocturnal, but may be active diurnally during the breeding season (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 668 pp.). We have no evidence to suggest whether the *D. punctatus* specimen was taken as carrion or predated. The worm-like appearance of *D. punctatus* might have elicited predation by *G. inscuplta*, or the snake might have been taken as carrion, possibly as the remnant of another predator's meal. Although a wide variety of vertebrates have been reported to prey on *D. punctatus*, the only reptile predators recorded are squamates (Ernst and Ernst 2003, *op. cit.*).

GOPHERUS AGASSIZII (Desert Tortoise). **BURROW ASSOCIATE**. Desert Tortoises are semi-fossorial and construct burrows that are a unique environment that provides shelter from the extreme heat and are generally more humid, both features which aid in reducing water loss (Bulova 2002. J.Therm. Biol. 27:175–789; Zimmerman et al. 1994. Herpetol. Monogr. 8:45–59). It would be expected that numerous other species would make use of this structure; however, in a review of burrow associates, Luckenbach (1982. *In* Bury [ed.], North American Tortoises: Conservation and Ecology, pp. 1–38. Wildl. Res. Report 12, U.S. Fish and Wildlife Service, Washington, D.C.) lists only 31 species observed in Desert Tortoise burrows. From this list we can conclude that virtually all desert vertebrates will use or modify a Desert Tortoise burrow for shelter, while only a few arthropods have been noted. This is rather surprising as more than 350 animals have been observed using burrows of the Gopher Tortoise (*Gopherus polyphemus*), with roughly 300 of these being invertebrates (Jackson and Milstrey 1989. *In* Diemer et al. [eds.], Gopher Tortoise Relocation Symposium Proceedings, pp. 86–98. State of Florida Game and Fresh Water Fish Commission Nongame Wildlife Program Technical Report No. 5). It is likely that part of this large discrepancy between the two species of tortoises' burrow associate fauna is based on the fact that the southwestern deserts of the United States are less diverse than the southeast, where the Gopher Tortoise is found. However, we believe that more invertebrates should be making use of Desert Tortoise burrows, despite the conclusions of Grant (1936. Zoologica 21:225–229) that burrow associates of the Desert Tortoise are not important.

On 13 November 2007 at 1200 h at a study site in the west Mojave Desert northeast of Barstow, San Bernardino County, California (Walde et al. 2007. West. N. Am. Nat. 67:147–149) we observed a tarantula (Araneae, Mygalomorphae, Theraphosidae) in a Desert Tortoise burrow. The tarantula was brown with a carapace of ca. 25 mm and was considered to be a male because of the relatively small abdomen. There are two species of tarantula in this area, *Aphonopelma mojave* and *A. iodius* (Prentice 1997. J. Arachnol. 25:137–176). These two species are easily distinguished as *A. mojave* is black and small, while *A. iodius* is larger and has a light to medium brown carapace with variably colored legs from medium to dark brown, to black (Prentice, *op. cit.*). Therefore, we can conclude that the tarantula observed in the burrow was *A. iodius*. These species are both fall breeders, a time when males go in search of females (Prentice, *op. cit.*), therefore it is likely that this *A. iodius* took refuge in the burrow during its mate searching, although it may have been looking for food. The burrow was an overwintering burrow for an adult female Desert Tortoise.

Previously, an unknown species of tarantula was documented in a Desert Tortoise burrow during a study in Nevada (Burge 1978. *In* Trotter [ed.], Desert Tortoise Council Proceedings of 1978 Symposium. pp. 80–111). To our knowledge, the only other spider documented in Desert Tortoise burrows is the Black-widow Spider (*Lactrodectus mactans*) which has been observed in California and Nevada (Burge, *op.cit.*; Luckenbach, *op. cit.*). The presence of these highly effective predators in the burrows of Desert Tortoises suggests that additional species of invertebrates are likely utilizing the burrows as well.

GOPHERUS AGASSIZII (Desert Tortoise). **PREDATION BY MOUNTAIN LION**. During a long-term study on tortoise growth within three fenced 9-ha enclosures in Rock Valley, Nevada Test Site (NTS), Nye County, Nevada, USA, tortoises have been captured annually since 1964 (Medica et al. 1975. Copeia 1975:630–643; Turner et al. 1987. Copeia 1987:974–979). Between early August and mid October 2003 we observed a significant mortality event. The Rock Valley enclosures were constructed of 6 x 6 mm mesh 1.2 m wide hardware cloth, buried 0.3 m in the soil with deflective flashing on both sides on the top to restrict the movement of small mammals and lizards from entering or leaving the enclosures (Rundel and Gibson 1996. Ecological Communities and Process in a Mojave Desert Ecosystem: Rock Valley, Nevada, Cambridge University Press, Great Britain. 369 pp.).

On 6 August 2003, the carcass of an adult female Desert Tortoise #1411 (carapace length 234 mm when alive) was collected while adult male tortoise #4414 (carapace length 269 mm) was observed alive and in good health on the same day. Subsequently, the carcass of #4414 was found on 16 October 2003. Between 16–17 October 2003, the remains of six (five adult and one juvenile) Desert Tortoises were found, some within each of the three enclosures in Rock Valley. A seventh adult tortoise was found on 26 September 2006, its death also attributed to the 2003 mortality event based upon the forensic evidence. Each of the seven adult Desert Tortoises had the central portion of their carapace broken open approximately to the dorsal portion of the marginal scutes while the plastron was still intact (Fig. 1A). Adjacent to seven of the eight remains, we located numerous bone fragments including parts of the carapace and limbs as well as dried intestinal content in nearby Range Rhatany (*Krameria parvifolia*) shrubs (Fig. 1B). The significance of the frequent use of this shrub is puzzling. Three of the Desert Tortoise shell remains possessed distinctive intercanine punctures measuring 55–60 mm center to center indicating that this was an adult sized Mountain Lion (*Puma concolor*). By comparison, a two-year old male Mountain Lion salvaged on NTS had an upper intercanine bite width of 45 mm, and a six-month old kitten measured 35 mm, respectively. The Mountain Lion is the only predator that exists in southern Nevada that could possibly have a bite with such a large gap between its upper canine teeth (Murmann et al. 2006. J. Forensic Sci. 51:846–860).

The appearance of the shell remains in Fig. 1A is similar to that depicting Jaguar (*Panthera onca*) predation on the Amazonian Red-footed Tortoise (*Geochelone denticulata*) as illustrated by Emmons (1989. J. Herpetol. 23:311–314), with the majority of the carapace broken open and the plastron still intact. Predation of Desert Tortoises by Mountain Lions was also documented in 1993 in southern Arizona (Little Shipp Wash Plot), where seven of eight carcasses found were attributed to Mountain Lion predation (Averill-Murray et al. 2002. *In* T. R.Van Devender [ed.], The Sonoran Desert Tortoise: Natural History, Biology, and Conservation, pp. 109–134. University of Arizona Press and Arizona-Sonora Desert Museum, Tucson, Arizona). Similarly, predation by a Mountain Lion has been reported on the Argentine Tortoise (*Chelonoidis chilensis*) in Argentina (Acosta et al. 2004. Herpetol. Rev. 35:53–54), and a Mountain Lion kitten was observed to kill and consume a portion of the carapace of a Texas Tortoise (*Gopherus berlandieri*) in west Texas (Adams et al. 2006. Southwest. Nat. 51:581–582).

Over the past 45 years this Desert Tortoise population has been monitored yearly, with no prior evidence of predation to tortoises within the fenced enclosures. On several occasions other predators such as Bobcats (*Lynx rufus*) have been observed within the study enclosures for as long as a week. Evidence of Kit Fox (*Vulpes macrotus*) sign has been observed on numerous occasions, and a Spotted Skunk (*Spilogale putorius*) and Longtail Weasels (*Mustela frenata*) have been captured and released (Medica 1990. Great Basin Nat. 50:83–84; B. G. Maza, pers. comm.), while Coyotes (*Canis latrans*) were never observed within the fenced enclosures. Prior to this predation event in Rock Valley, 17 Desert Tortoises were alive between 2000 and 2002, only 7 were known to be alive in 2004, while 2 tortoises have not been seen since 2002. Predation studies of Mountain Lions indicate that these events may be an example of a learned behavior of individual animals developing

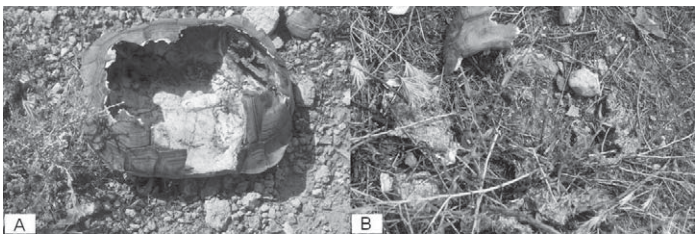

FIG. 1. A) Shell remains of an adult female Desert Tortoise (#1411) characteristic of Mountain Lion predation. B) Pieces of Desert Tortoise carapace and remnants of intestinal content found in a *Krameria parvifolia* shrub.

a preference for a prey (Logan and Sweanor 2001. Desert Puma: Evolutionary Ecology and Conservation of an Enduring Carnivore. Hornocker Wildlife Institute, Island Press, Washington. 463 pp.; Creeden and Graham 1997. Desert Bighorn Council Transactions, pp. 37–43), or the plight of a large predator locating an available source of food while passing through low elevation Mojave Desert habitat in late summer or early fall. Several Mountain Lion sightings were recently recorded in late summer and early spring (5 and 26 July 2006; 15 March 2007) at lower elevations (1300 m) in *Larrea*/*Ambrosia* habitat on the NTS, 8–10 km NE of Rock Valley in canyons near the base of Skull Mountain. Predation upon Desert Tortoises and their nests is also perpetrated by smaller carnivores, e.g., Coyotes, Kit Foxes, and Badgers (Grover and DeFalco 1995. Desert Tortoise (*Gopherus agassizii*): Status-of-knowledge Outline with References. U.S. Department of Agriculture, Forest Service Report INT-GTR-316, pp.76–79). Predation by these smaller carnivores generally leaves the carapace intact and the head and legs are gnawed off, sometimes leaving the upper portions of the appendages still connected to the carcass. The carcass of an adult male tortoise #1212 (carapace length 289 mm when last captured alive) was found in this condition on 15 October 2004. Such predation events upon alternate prey such as the Desert Tortoises appear to take place toward the end of the summer season and coincide with a combination of drought years and the reduced density of typical prey such as small mammals. Localized predation events by a large predator such as Mountain Lions can have a significant impact upon on a small population of prey, e.g., the reduction of the population of bighorn sheep in the Granite Mountains during drought 1989–1991 (Wehausen 1996. Wildl. Soc. Bull. 24:471–479). The Mountain Lion predation event that took place in Rock Valley during 2003 was likely a chance happening but has had a profound impact upon the local population. The presence of Bighorn Sheep (*Ovis canadensis*) in the adjacent Specter Range since their introduction in the fall of 1990 may have influenced the distribution of Mountain Lions.

We thank E. Boydston, D. Hall, D. Hansen, and K. Nussear for reviewing this note. Additionally, we thank the numerous dedicated individuals that have volunteered to assist in the recapture of the Rock Valley Desert Tortoises, particularly J. Burroughs, M. Burroughs, K. Murphy, and K. Drake. We thank K. Nolte for preparing the figures. This study was conducted under Fish and Wildlife Service, U.S. Threatened Species Permit TE 759747, and Nevada Division of Wildlife Permits S-21692, S-24391, and S-28154 issued to (PAM). We gratefully acknowledge the U.S. Department of Energy, National Nuclear Security Administration for continued access to the study area. This manuscript (DOE/NV/25946-494)

GOPHERUS POLYPHEMUS (Gopher Tortoise). **EMERGENCE BEHAVIOR**. Female Gopher Tortoises often place their nests in a mound of soil or bare area (referred to as the "apron") located immediately in front of their burrows (studies reviewed in Mushinsky et al. 2006. *In* Meylan [ed.], Biology and Conservation of Florida Turtles, pp. 350–375. Chelonian Research Foundation, Lunenburg, Massachusetts). However, observations of nest emergence and subsequent behavior of hatchling Gopher Tortoises are few. To our knowledge, Ashton and Ashton (2008. The Natural History and Management of the Gopher Tortoise. Krieger Publishing Company, Malabar, Florida) provide the only account of a hatchling Gopher Tortoise entering an active adult burrow immediately following nest emergence. We observed a hatchling Gopher Tortoise emerge from a nest located on a female tortoise burrow apron while an adult male courted the resident female and document the hatchling's emergence, the male's response, and the hatchling's post-emergence use of the active adult burrow.

We made our observation using an automated video system focused on an adult female burrow at the Camp Shelby Joint Forces Training Center in southern Mississippi, USA. On 26 August 2006 at 1229 h (CST; overcast skies; ambient air temperature [T_a] = 30ºC), an adult male was on a burrow apron courting an adult female that was inside her burrow as a hatchling Gopher Tortoise emerged from its nest, located about ~10 cm in front of the male. The female, which entered her burrow earlier, did not emerge while the hatchling was present. The male head bobbed intermittently before, during, and after the emergence event. Although he was directly facing the hatchling and head bobbing in its direction, he was probably directing this behavior toward the female's burrow, which was also in front of him. The male extended his head toward the hatchling three times. All but the third head extension could easily have been part of the courtship ritual, but the third appeared to be clearly in response to the hatchling as the male extended his head far forward and touched the small turtle with its nose for several seconds. To our knowledge, this is the first report of an adult Gopher Tortoise responding to the presence of a hatchling. We did not identify any other unambiguous response by the adult toward the hatchling. The hatchling moved toward the male, and the male also moved slightly toward it (and the female burrow) until the hatchling was just in front of the male's gular and left forelimb. The two tortoises appeared to repeatedly make random contact before the hatchling walked away.

The male then proceeded toward the burrow, inadvertently pushing the hatchling that was still in his path with his forelimb and shell as he walked by. The hatchling, now behind the male, followed. The male continued to head bob toward the female's burrow and disappeared into the burrow at 1241 h. The hatchling appeared to enter the burrow at 1242 h, but it is unknown if it completely entered the burrow because the camera was positioned slightly behind the burrow entrance. The hatchling intermittently appeared in the burrow entrance until 1246 h, when it was no longer visible. A short while later, a small tortoise, possibly the same hatchling, emerged from the burrow entrance before going back inside. At 1255 h, shortly after it started to rain, the male emerged from the burrow and left the apron and the video-taped area. At 1305 h (T_a = 27ºC), while it was still raining, a small tortoise (possibly the same hatchling) emerged from the burrow entrance. After beginning to leave the apron, it turned around and somehow, perhaps due to the slope of the terrain, overturned onto its carapace. Thirty seconds later, the hatchling righted itself, left the apron, and went into some dense vegetation before going out of view for the final time at 1329 h. Neither the male nor the hatchling returned to the burrow later that day before the video system stopped recording at 2030 h.

Ashton and Ashton (*op. cit*.) report an event in which a hatchling entered an active adult burrow immediately upon emerging from its nest. It is unknown whether a hatchling that is at the surface can determine whether a burrow contains an adult tortoise. Our observation of a hatchling following an adult tortoise into a burrow entrance is notable because it provides unambiguous evidence that upon emergence, some hatchlings use adult burrow entrances (and probably deeper portions of burrows also) regardless of activity status or adult presence at the burrow mouth. Adult Gopher Tortoise burrows may provide newly-emerged hatchlings with a convenient, temporary refuge from hot and dry surface conditions from which they can leave to construct their own burrows when conditions are favorable for extended above ground activity.

We thank T. Borries, A. Holbrook, D. Jackan, J. Lee, B. Madden, A. Portoluri, J. Smolinsky, and N. VandenBroek for valuable assistance in the field. We also thank the Mississippi Army National Guard for their continued support of tortoise conservation efforts on CSJFTC. The U.S. Army Construction Engineering Research Laboratory provided funding for this research. This research was conducted under a scientific research permit from the Mississippi Museum of Natural Science.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **NESTING.** *Gopherus polyphemus* is endemic to the Longleaf Pine ecosystems of the Gulf Coastal Plain of the southeastern USA. Oviposition in this species usually occurs between May and early July when eggs are deposited in a nest cavity usually located on the apron of

the burrow. In the DeSoto National Forest (DNF), female tortoises construct nest cavities on average 55 cm from the mouth of the burrow, 17 cm deep, and containing 5 eggs (Noel 2006. Unpubl. MS thesis, University of Southern Mississippi, Hattiesburg). During the summer of 2008, we searched burrow aprons in the DNF for clutches of eggs on a daily basis. Each clutch that was found was excavated and removed from the nest cavity and moved to man-made nests at different burrows, as part of an experiment to evaluate environmental influences on hatching success. Following excavation and egg removal, nest cavities were re-filled with the loose soil that had been earlier removed. Because of the soil composition and hard-setting nature of most burrow aprons (mean soil composition of nests: 83.2% sand, 12.7% silt, and 4.1% clay), these nest cavities often remain detectable by feel (i.e., a hard-sided cavity filled with loose, friable soil) for several weeks or longer.

On 24 May 2008, a clutch (N = 5 eggs) was found and excavated at a burrow (#7032 in the DNF database) at our McLaurin site (31.14992 Nº, 89.2005 Wº) that was ca. 70 cm from the burrow mouth and 17 cm deep. Ten days later on 3 June 2008, a second clutch (N = 6) was discovered within the same nest cavity, with only minor modifications to the original shape. A third clutch (N = 5) was excavated from the same nest cavity just two days later on 5 June 2008 with slightly more substantial modifications to the original cavity. The final clutch (N = 5) was discovered on 16 June 2008 at the original cavity location; however the cavity was highly modified from the original shape and size. To our knowledge, this is the first report of multiple clutches being laid not only at the same burrow but also in the same nest cavity within a given year. We presume that these four clutches were oviposited by four different females, since there are no published accounts of multiple clutches in one season for *G. polyphemus*, and it seems highly unlikely that a female could produce a subsequent clutch in as few as two to eleven days. This is perhaps not a naturally occurring phenomenon, since we removed each previous clutch, the presence of which may have prevented subsequent females from excavating and ovipositing in the same location. Alternatively, it is possible that subsequent females may have used the same location even without our alterations, perhaps destroying the prior clutch(es) during their excavation of a nest cavity. During our five years (2003–2007) of searching for nests at the same sites, we have never found a nest cavity utilized more than once but have found, on several occasions, two clutches oviposited in the same apron. These observations suggest that particular burrow aprons could be more favorable, and nesting *G. polyphemus* may exhibit preference for these locations.

The research that led to this observation was conducted under a Mississippi Administrative Scientific Research Collection Permit for nesting experiments with *G. polyphemus*. This research was funded by the U.S. Army Corps of Engineers Construction Engineering Research Laboratory, contract number W9132T-06-2-0021, and in earlier years (2003–2005) by the Mississippi Department of Wildlife, Fisheries, and Parks. We thank Brian Kreiser for reviewing this document.

Submitted by **JOSHUA R. ENNEN** (e-mail: joshua.ennen@usm.edu), **JENNIFER LAMB**, and **CARL P. QUALLS**, Department of Biological Sciences, University of Southern Mississippi, 118 College Drive #5018, Hattiesburg, Mississippi 39406-0001, USA.

GRAPTEMYS FLAVIMACULATA (Yellow-blotched Map Turtle). **UNUSUAL BASKING DISTURBANCE.** Members of the genus *Graptemys* are noted for their proclivity to bask aerially and wariness while basking on emergent deadwood (Boyer 1965. Ecology 46:99–118). Basking disturbances for this species have been studied, but focused on human recreational disturbance (Moore and Seigel 2006. Biol. Cons. 130:386–393). Here we report multiple observations of *G. flavimaculata* basking disturbances caused by unnatural floating debris.

On 23 June 2007, three male *G. flavimaculata* (West Pascagoula River, Jackson County, Mississippi) were observed to flee their basking locations in response to a large piece of polystyrene foam (ca. 90 x 90 x 90 cm) floating downstream at 1755 h. One of these turtles was basking in a fallen tree crown and two were basking on the trunk portion of the same fallen tree. Also, on 22 April 2008 (same locale), two female, one male, and one juvenile female *G. flavimaculata* were not disturbed by a medium-sized piece of floating polystyrene foam (122 x 45 x 20 cm) floating downstream at 1339 h. However, this floating debris got caught in an eddy current and began moving back upstream and only then (1343 h) did all four individuals evacuate their basking locations on trunk portions of fallen trees. Later that afternoon at 1730 h, three female *G. flavimaculata* were disturbed by a small piece of Styrofoam (45 x 15 x 10 cm) floating downstream.

On 20 April 2008, a large female *G. flavimaculata* (same locale) was disturbed from her basking location because of a large television floating downstream at 1304 h. Further, it was also noted that two *G. flavimaculata* males basking downstream were not disturbed by the same floating television at 1310 h.

Within the Lower Pascagoula River, there are many floating houseboats and these usually have large blocks of polystyrene foam that are used for floatation. Following Hurricane Katrina, many of these houseboats were destroyed (by wind and storm surge) and there was a plethora of floating debris including plywood, couches, polystyrene foam, and other items. For all observations, objects passed within 5–10 m of the basking turtles, and therefore, it is unknown if objects floating at greater distance would elicit the same response. However, it is clear from these observations that this species is quite wary of unnatural floating items in the river.

Submitted by **WILL SELMAN, DUSTIN STRONG,** and **CARL QUALLS**, Department of Biological Sciences, Box 5018, University of Southern Mississippi, Hattiesburg, Mississippi 39401, USA (e-mail: will.selman@usm.edu).

GRAPTEMYS FLAVIMACULATA (Yellow-blotched Map Turtle). **BASKING AND PARASITE REMOVAL**. Aerial basking in turtles is thought to be primarily for thermoregulatory reasons (Boyer 1965. Ecology 46:99–118). However, a recent observation (Selman et al. 2008. Herpetol. Rev. 39:216) supports the secondary role of basking as a method to rid turtles of ectoparasites (Cagle 1950. Ecol. Monogr. 20:31–54; Neill and Allen 1954. Ecology 35:581–584; Vogt 1979. Auk 96:608–609). Here, we provide a second observation of voluntary leech removal from a different species in the genus *Graptemys*.

On 27 May 2008 (1127 h), WS observed a juvenile female *Graptemys flavimaculata* (~10 cm, 200 g) basking on a branch of a fallen tree-crown (West Pascagoula River, Jackson Co., Missis-

sippi, USA). It was unknown how long the individual had been emerged from the water, but the shell was completely dry when first observed. Also, a large leech (*Placobdella* sp.) was noted on the posterior right portion of the carapace and it was in a ball shaped posture, presumably for water conservation. After 6 minutes of observation (1133 h), the leech terminated the ball-shape and moved slowly toward the posterior of the carapace. Over the next minute, the leech removed one end of its body from of the turtle and began to 'search' below toward the branch, while the other end was still attached at the rear margin of the carapace. The leech tried to reach for the branch multiple times to remove itself, but was unsuccessful because the turtle was 'swiping' her hind legs, preventing the leech from attaching to the log. At 1134 h, the leech began to 'search' again for the branch and the turtle flipped the leech off its shell with a swipe of its right hindlimb into the water.

At the time of basking, the air temperature was 27.2°C and log surface temperature was 28.2°C. Therefore, the carapace temperature of the *G. flavimaculata* juvenile female was likely hot enough to induce the leech to voluntarily release itself from its host organism. It is unlikely that the leg swiping was related to the leech's presence, but instead a normal behavior associated with basking in other turtle species (Auth 1975. Bull. Florida St. Mus. 20:1–45). We assume that the leech eventually would have removed itself in a manner similar to our previous observation (Selman et al. 2008, *op. cit*.) had the turtle not assisted. This is the second documented observation of voluntary parasite release during basking and first observation for this species.

Submitted by **WILL SELMAN** and **CARL QUALLS**, Department of Biological Sciences, Box 5018, University of Southern Mississippi, Hattiesburg, Mississippi 39401, USA (e-mail: will.selman@usm.edu).

MACROCHELYS TEMMINCKII (Alligator Snapping Turtle). **ADULT BASKING BEHAVIOR**. *Macrochelys temminckii* is the largest freshwater turtle in North America, inhabiting rivers and associated waters (e.g., cypress swamps and smaller tributaries) that drain into the Gulf of Mexico (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institute Press, Washington, D.C. 578 pp.). Little is known concerning the behavior of this secretive turtle, but there have been reports of *M. temminckii* hatchlings and juveniles basking aerially (Ewert 1976. Herpetologica 32:150–156; Farr et al. 2005. Herpetol. Rev. 36:168; Shelby and Jenson 2002. Herpetol. Rev. 33:304). Here we report the first known aerial basking observation of an adult *M. temminckii*.

On 3 April 2008 (1400 h), WS and BD observed an adult *M. temminckii* (ca. 40–50 cm carapace length) basking on a bank of the Leaf River (Forrest County, Mississippi, USA). The individual was observed via spotting scope (ca. 100 m distant), ca. 1.8 m above the water's surface on the opposite, cut bank side of the river. The individual was facing upslope and appeared lifeless, with head extended completely and resting on the sand bank (to the extent that we could seeing the complete dorsal profile of the head). The sandy bank was fully exposed to sun, non-vegetated, had a slope of ca. 45–60°, and faced to the southwest. Conditions were mostly sunny, with a water temperature of 22°C and an ambient air temperature of 28°C (31°C in direct sunlight). After observation of this turtle basking for ca. 5 minutes, it turned around and retreated to the water. The route back to the water seemed to be a "controlled fall" on the steep slope and the turtle hesitated slightly before re-entering the water.

It is unlikely that this behavior was associated with female reproductive activity because reports indicate that nesting of *M. temminckii* occurs in Florida during late April to early May (Ewert and Jackson 1994. Unpubl. report to Florida Game and Freshwater Fish Commission) and in Georgia until early June (Powders 1978. Copeia 1978:134–140). Furthermore, subsequent searches did not reveal any nest sites at the basking location. It is difficult to determine what initiated this behavior because there are no other reports for adult basking behavior. We could not determine how long the individual had been basking before our initial observation or why the turtle was basking so far and high from the water's edge on a steep inclined river bank, as opposed to near the water's edge. However, we presume that basking behavior could have been initiated due a combination of factors. The day of observation was mostly sunny, preceded by three days of cloudy conditions. Water temperatures were relatively low, and river flows peaked during the day of observation, preceded by two days of rising water levels following heavy rains. Additionally, the individual might have had an injury or illness and might have been basking to increase body temperature to fight infection.

We thank Dale Jackson, Bob Jones, and Tom Mann for providing information and suggestions pertaining to this observation.

Submitted by **WILL SELMAN**, **BRANDON DRESCHER**, and **CARL QUALLS**, Department of Biological Sciences, Box 5018, University of Southern Mississippi, Hattiesburg, Mississippi 39401, USA (e-mail: will.selman@usm.edu).

PSEUDEMYS CONCINNA (River Cooter). **MAXIMUM BASKING TIME.** *Pseudemys concinna* is a large, herbivorous, freshwater turtle that is found predominantly in the southeastern United States (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 578 pp.). It is prone to aerial basking and this behavior has been observed in West Virginia populations from March to September (Buhlman and Vaughan 1991. J. Herpetol. 25:72–78), with basking peaking during midday (1200 h) for Florida populations (Pritchard and Greenhood 1968. Int. Turtle Tortoise Soc. J. 2:20–25, 34). Even though it is known that basking behavior is common in this species, the maximum amount of time an individual will spend once emerged from the water is unknown. Here we report a maximum basking time for this species.

On 15 April 2008 (Leaf River, Forrest County, Mississippi, USA), a *P. concinna* (ca. 15–20 cm CL) was noted emerging onto a branch at 0950 h, which was the first favorable sunlight conditions for basking. This individual basked without re-entering the water until 1755 h (8 h, 5 minutes). At the time of emergence, the water temperature was 16.3°C and the ambient air temperature was 12°C (26.6°C in sunlit conditions). At submergence, water temperature was 20.0°C and ambient air temperature was 17.4°C (33.7°C in sunlit conditions). Furthermore, it was sunny throughout the day; the water temperature peaked at 20.0°C and ambient air temperatures peaked at 18.1°C (sunlit temperatures at 34.7°C).

Throughout the day, many *P. concinna* were observed basking

for extended periods of time (4–6 h). Also, 44 *P. concinna* were noted basking at 1400 h along a 310-m section of river. This was the most observed during any hourly count at this location throughout the year (April–October). Therefore, early spring, when water temperatures are cool and air temperatures are warming, is apparently highly conducive to *P. concinna* basking for long periods of time.

Submitted by **WILL SELMAN** and **CARL QUALLS**, Department of Biological Sciences, Box #5018, University of Southern Mississippi, Hattiesburg, Mississippi 39401, USA (e-mail: will.selman@usm.edu).

TERRAPENE ORNATA LUTEOLA (Desert Box Turtle). **CARRION FEEDING**. *Terrapene ornata* is known to eat a variety of food items, although its diet mainly consists of insects under natural conditions (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, 578 pp.; Legler 1960. Univ. Kansas Publ., Mus. Nat. Hist. 11:527–669). Included in the diet of the species is carrion (Dodd 2001. North American Box Turtles: A Natural History. Univ. of Oklahoma Press, Norman, 231 pp.). *Terrapene ornata luteola* occurs in desert habitats of New Mexico, Texas, Arizona, and adjacent parts of Mexico. Most information on the diet of *T. ornata* has been gathered on the grassland-inhabiting subspecies *T. o. ornata*. Here I report on an instance of carrion feeding in *T. ornata luteola*.

On 22 July 2008 at 0716 h, at the Sevilleta National Wildlife Refuge (ca. 67 km S of Albuquerque, New Mexico, USA), I found an adult female *T. ornata luteola* (130 mm straight-line carapace length, 583 g) on a dirt road with the head of a recently deceased Round-tailed Horned Lizard (*Phrynosoma modestum*) in its mouth. When I drove up to the turtle, she started to move off the road with the lizard still in her grasp. The female held onto the lizard for about 30 s as I tried to photograph her. Once she dropped the lizard, I placed turtle and lizard in a holding box. A small (about 4 mm) chunk of the anterior portion of the head of the lizard had been removed. The horned lizard (58 mm snout–vent length, 6.2 g) was still pliable and may have been a recent roadkill. However, a caged *T. o. ornata* was found to have partially eaten a living Texas Horned Lizard (*P. cornutum*) caged with it (Eaton 1947. Copeia 1947:270). Under natural conditions, though, it seems unlikely that a turtle could catch a living horned lizard.

Submitted by **DAVID J. GERMANO**, Department of Biology, California State University, Bakersfield, California 93311, USA; e-mail: Dgermano@csub.edu.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). **MAXIMUM BASKING DURATION.** *Trachemys scripta* is a large, omnivorous, freshwater turtle that is found predominantly in the southeastern and central United States (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 578 pp.), although it has been introduced to many places worldwide via the pet and food trades (Emer 2004. Herpetol. Rev. 35:34–35; Lever 2003. Naturalized Reptiles and Amphibians of the World. Oxford University Press, Oxford; Perry et al. 2007. Applied Herpetol. 4:88–89). Aerial basking is highly developed in this species with peak basking time occurring around 1400 h; maximum basking duration also has been noted at over 200 minutes during the fall months (Auth 1975. Bull. Florida St. Mus. 20:1–45). Here we report a new maximum basking time for this species.

On 15 April 2008 (Leaf River, Forrest County, Mississippi, USA), a *T. s. elegans* (ca. 20 cm CL) was noted emerging onto a branch at 0955 h—the first favorable sunlight conditions for basking. This individual basked without re-entering the water until 1705 h (7 h, 10 minutes). At the time of turtle emergence, water temperature was 16.4°C and the ambient air temperature was 12.4°C (26.4°C in sunlit conditions). At submergence, water temperature was 19.9°C and ambient air temperature was 17.5°C (33.6°C in sunlit conditions). Further, it was sunny throughout the day; water temperature peaked at 20.0°C and ambient air temperatures peaked at 18.1°C (sunlit temperatures at 33.6°C).

Throughout the day, many turtles of several species were noted to bask for extended periods of time (4–6 h). Therefore, early spring, when water temperatures are cool and air temperatures are warm, appear highly conducive to extended basking in *T. s. elegans* and other co-occurring turtle species.

Submitted by **WILL SELMAN** and **CARL QUALLS**, Department of Biological Sciences, Box 5018, University of Southern Mississippi, Hattiesburg, Mississippi 39401, USA (e-mail: will.selman@usm.edu).

CROCODYLIA — CROCODILIANS

CAIMAN CROCODILUS **(**Spectacled Caiman**). OPPORTUNISTIC FORAGING.** We document opportunistic foraging behavior by *Caiman crocodilus* in a post-inundation forest at Estacíon Biologíca Caño Palma, Costa Rica. Estacíon Biologíca Caño Palma is a 40-ha reserve located on the northeast coast of Costa Rica, south of Barra del Colorado. This reserve and the surrounding area is lowland tropical wet forest (*fide* Holdridge 1967. Lifezone Ecology, Tropical Science Center, San José, Costa Rica. 206 pp.) comprised predominantly of *Manicaria* swamp forest (Myers 1990. *In* Lugo et al. [eds.], Ecosystems of the World, pp. 267–278. Elsevier, Oxford, UK). Bounded by large catchment rivers to the north, south, and west with a blackwater channel to the east, the forest inundates seasonally (November–December and May). *Manicaria* forests typically exhibit a prominent biannual polymodal inundation during the wettest season (Junk et al. 2000. The Central Amazon Floodplain: Actual Use and Options for a Sustainable Management, Backhuys Publishers, Leiden, Holland. 584 pp.). The seasonal inundation event that engulfs Estacíon Biologíca Caño Palma is also coupled with local tidal flow patterns (Kelso 1967. Unpubl. M.Sc. thesis, Univ. Florida, Gainesville. 156 pp.). Once inundation subsides, numerous temporal pools remain in the forest; these generally disappear during the warmer (and drier) months of the year.

In December 2002 and again in January 2004, during three months of weekly diurnal visual-encounter transects of post-inundation *Manicaria* forest, 5 adult and 7 juvenile caiman (2002) and 4 adult and 3 juvenile caiman (2004), respectively, were located well into (often > 100 m) the forest. Once disturbed, they retreated terrestrially toward the channel associated with riparian habitat, rapidly slipping in and out of temporary pools as they headed in an easterly direction toward the main blackwater channel bordering the property.

Caiman reproduction, which generally occurs during the rainy season in this region of Costa Rica (November–February), involves construction of vegetation mounds in forested environments to incubate the eggs (Allsteadt 1994. J. Herpetol. 22:12–19). As in other crocodilians, caiman exhibit well-developed parental care and will defend nests from predators, the primary threat to their eggs (Leenders 2001. A Guide to Amphibians and Reptiles of Costa Rica. Zona Tropical, Miami, Florida. 305 pp.). We detected no evidence of nests or nest-guarding behavior in the areas where we sighted caiman. However, these areas, still saturated by water, were frequently found to be full of suffocating fish trapped in desiccating flood pools or anurans utilizing these ponds for breeding. Fish species present included: *Archocentrus nigrofasciatus* and *Parachromis managuensis* (Cichlidae), *Rhamdia guatemalensis* and *Rhamdia rogersi* (Pimelodidae), and *Astyanax aeneus* (Characidae). *Atractosteus tropicus* (Order: Semionotiformes) were also hunting in these pools and may have constituted prey. That caiman were feeding on the diverse prey within these seasonally restricted environments seems likely. Fish are an important prey species for many crocodilians (Magnusson 1987. J. Herpetol. 21:85–95) and can make up over 25% of total prey items in sub-adult and mature adult caiman (Thorbjarnarson 1993. Herpetologica 49:108–117; Velasco et al. 1994. Crocodile Specialist Group Newsletter 13:20–21). In tropical blackwaters Cichlidae, Pimelodidae, and Characidae can make up 10–27% of the composition of fish species consumed (Santos et al. 1996. Herpetol. J. 6:111–117; Thorbjarnarson 1993. Herpetologica 49:108–117) and possibly more when increases in water level like that which occurred along the Caño Palma allow more fish access to greater volumes of water and increased predation susceptibility (Silveira and Magnusson 1999. J. Herpetol. 33:181–192).

Caiman now occur in diverse habitats such as marshes, rivers, channels, and lakes in both the Caribbean and Pacific lowlands of Costa Rica, particularly as a result of the now-diminished ranges of sympatric competitors (*Crocodylus acutus*) (Magnusson 1982. Crocodiles, pp. 108–116. Proc. 5th IUCN/SSC Croc. Spec. Group, Gland, Switzerland). They are commonly found in the canals, dykes, and channel networks in forested floodplain habitats (Allsteadt and Vaughan 1992. Brenesia 38:65–69; Guyer 1994. *In* McDade et al. [eds.], La Selva: Ecology and Natural History of a Neotropical Rain Forest, pp. 210–216. Univ. Chicago Press, Chicago, Illinois; Guyer and Donnelly 2005. Amphibians and Reptiles of La Selva, Costa Rica and the Caribbean Slope. Univ. California Press, Berkeley, California. 299 pp.; Ouboter and Nanhoe 1988. J. Herpetol. 22:283–294; Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Illinois. 934 pp.). This species is known to establish territories in local channel networks where they exhibit high site tenacity (Savage, *op. cit.*), especially in areas that provide a sustainable food resource. Opportunistic seasonal shifts in habitat use has not been widely reported in *Caiman crocodilus*. Our observations imply that these habitat shifts provide enhanced feeding opportunities that may be unavailable the rest of the year. We present two models that may explain these habitat shifts. In the first, caiman may periodically abandon their territories within the permanent channel network during episodic inundation to specifically forage for trapped fish within temporary pools in the forest. The second model proposes that caiman along with other fauna advance into the forest during inundation following the expanding shoreline. As the water recedes, some aquatic animals are trapped in pools where they are vulnerable to amphibious predators, such as caiman. Caiman are able to escape back to traditional channel-margin habitat as the pools disappear. Which is correct provides an interesting question for further research.

We thank The Canadian Organization for Tropical Education and Rainforest Conservation for permission to study at Caño Palma Biological station, Xavier Guevara of The Ministerio de Recursos Naturales Energia y Minas for permitting licences, and Farnborough College of Science and Technology for assistance.

LACERTILIA — LIZARDS

AMEIVA FESTIVA (Middle American Ameiva). **ENDOPARASITES.** *Ameiva festiva*, a diurnal forest species, occurs in humid lowlands from Tabasco, Mexico to northern Colombia (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). To our knowledge, only one report exists of helminths in *A. festiva*; Bursey et al. (2006. J. Parasitol. 92:350–353) reported the nematode *Oswaldocruzia nicaraguensis*, physalopterid (nematode) larvae and an acanthocephalan cystacanth from *A. festiva* collected in Nicaragua. The purpose of this note is to add the nematode *Physaloptera retusa* to the list of endoparasites for *A. festiva*.

Only the stomach of one *A. festiva* female (90 mm SVL) deposited in the Natural History Museum of Los Angeles County, Los Angeles, California, USA as LACM 72804 (from Colombia, Chocó Province, upper Rio del Valle, 06.7572°N, 77.5636°W, WGS84; elev. 50 m) collected in 1971 was opened and examined for helminths. Found were 5 adult (4 male, 1 female) nematodes, which were cleared in a drop of glycerol on a glass slide, cover-slipped and identified using a compound microscope as *Physaloptera retusa.* Nematodes were deposited in the United States National Parasite Collection, Beltsville, Maryland as: *Physaloptera retusa* (USNPC 101082).

Physaloptera retusa is widely distributed among lizards in the western hemisphere (Baker 1987. Mem. Univ. Newfoundland, Occas Pap. Biol. 11:1–325; Goldberg et al. 2007. Comp. Parasitol. 74:327–342). Physalopterid nematodes utilize insects as intermediate hosts; lizards become infected by ingesting insects containing infective larvae (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission, 2nd ed. CABI Publishing, Oxfordshire, UK. 650 pp.). *Ameiva festiva* represents a new host record for *P. retusa*. Colombia is a new locality record.

We thank Christine Thacker (LACM) for permission to examine *A. festiva.*

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

AMEIVA UNDULATA (Rainbow Ameiva). **ENDOPARASITES.** *Ameiva undulata* is known from Tamualipas and Nayarit, Mexico, south to Nicaragua (Savage 2002. The Amphibians and Reptiles of Costa Rica; A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). To our knowledge, only one report exists of an endoparasite from this species. Caballero (1951. Ann. Instit. Biol. Univ. Nac. Aut. Mexico 20:141–158) reported the nematode *Physaloptera retusa*. The purpose of this note is to add the nematode *Physalopteroides venancioi* and an acanthocephalan (Oligacanthorhynchidae) cystacanth to the list of endoparasites from *A. undulata*.

The coelomic cavities of 28 *A. undulata* from Guanacaste Province, Costa Rica in the herpetological collection of the Natural History Museum of Los Angeles County were examined for helminths. The body cavity was opened and the coelomic cavity and visceral organs were examined. Three female nematodes were found, two from LACM 166050 (male, 76 mm SVL) and one from LACM 166081 (male, 68 mm SVL) both collected 1964 (vic. Liberia, 10.6333°N, 85.4333°W, WGS84; elev. 176 m) and one acanthocephalan cystacanth was found in LACM 166089 (male, 103 mm SVL) collected 1983 (vic. Bagaces, 10.3333°N, 85.3333°W; elev. 400 m). Nematodes were cleared in a drop of glycerol on a glass slide, cover-slipped and identified using a compound microscope as *P. venancioi*. The acanthocephalan was regressively stained in hematoxylin, mounted on a glass slide in a drop of Canada balsam, cover-slipped and identified using a compound microscope as a cystacanth belonging to the Oligacanthorhynchidae. Endoparasites were deposited in the United States National Parasite Collection, Beltsville, Maryland as: *P. venancioi* (USNPC 101073) and (Oligacanthorhynchidae) cystacanth (USNPC 101074).

Physalopteroides venancioi was described from *Bufo paracnemis* (currently *Rhinella schneideri*) from Paraguay (Lent et al. 1946. Mem. Instit. Oswaldo Cruz. 44:195–214) and is also known from anurans and lizards from Peru as well as lizards from Brazil (Bursey et al. 2005. Comp. Parasitol. 72:50–68). It is in the family Physalopteridae which typically utilize insect intermediate hosts (Anderson 2000. Nematode Parasites of Vertebrates; Their Development and Transmission, 2nd ed. CABI Publishing, Oxfordshire, UK. 650 pp.). The cystacanth, a larval acanthocephalan, also requires an arthropod intermediate host (Kennedy 2006. Ecology of the Acanthocephala. University Press, Cambridge, UK. 249 pp.). *Ameiva undulata* represents a new host record for *P. venancioi* and oligacanthorhynchid cystacanth.

We thank Christine Thacker (LACM) for permission to examine *A. undulata* which is part of the CRE collection donated to LACM in 1998 by Jay Savage.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology. Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA.

AMPHIBOLURUS MURICATUS (Jacky Dragon). **AVIAN PREDATION**. The Jacky Dragon, a medium-sized agamid lizard (100 mm SVL; tail length: ~200% SVL), is common in heathland regions of southeastern coastal Australia. As with many agamids, they rely heavily on their motion vision system for survival. They adopt a sit-and-wait strategy to identify insect prey, waiting for movement to attract their attention. They also respond to the movement of larger animals that may pose a threat, including birds, larger reptiles, and mammals. While Jacky Dragons are abundant and detailed knowledge of their behavior and reproductive biology exists (e.g., Harlow and Taylor 2000. Austral Ecol. 25:640–652; Peters et al. 2007. Curr. Biol. 17:1231–1234; Warner and Shine 2008. Nature 451:566–568), scant data exist on predation. To our knowledge, there is only a recent note on predation by varanid lizards *Varanus rosenbergi* and *V. varius* (Warner 2007. Herpetol. Rev. 38:449). That report describes predation following raids on nests that were likely identified using chemical cues. Though larger reptiles such as varanid lizards and snakes may feed opportunistically on agamid lizards (e.g., Shine 1977. Can. J. Zool. 55:1118–1128), our observations in the field suggest that Jacky Dragons are particularly responsive to potential aerial predators. Indeed, raptors such as Australian (Nankeen) Kestrels (*Falco cenchroides*) and White-bellied Sea-eagles (*Haliaeetus leucogaster*) frequently hover and circle above our outdoor field enclosures and are watched intently. Dietary analyses of many Australian raptors provide evidence that agamid lizards are preyed upon (Marchant and Higgins 1993. Handbook of Australian, New Zealand and Antarctic Birds. Vol 2. Raptors to Lapwings. Oxford University Press, Melbourne, Australia. 984 pp.), but identification of remains has not reached the species level. Here we document predation on a Jacky Dragon by another common Australian bird, the Laughing Kookaburra (*Dacelo novaeguineae* – hereafter Kookaburra).

The Kookaburra is an ambush predator and, although primarily insectivorous, they will take vertebrates, including snakes of more than twice their weight (Blomberg and Shine 2000. Behav. Ecol. Sociobiol. 48:484–489). Small prey are swallowed whole, whereas larger prey are first killed by being beaten against the ground or a tree branch. During the afternoon of 14 September 2006, we observed a Kookaburra manipulating a live adult Jacky Dragon in

FIG. 1. A Jacky Dragon (*Amphibolurus muricatus*) in the beak of a Laughing Kookaburra (*Dacelo novaeguineae*).

its beak at Tura Head Coastal Reserve, New South Wales, Australia (36.82°S, 149.93°E; elev. 20 m) (Fig. 1). The kookaburra remained on the same perch, occasionally beating the Jacky Dragon against the tree branch, and consuming it over the following two hours.

Jacky Dragon color patterns ensure that they remain cryptic while basking motionless in dense habitats; territorial defense behavior, however, quickly disrupts their camouflage. This suggests a direct cost for intra-species aggression. Like many lizards, Jacky Dragons make use of their motion vision system by relying on movement to communicate. In response to potential rivals, they perform a stereotyped display comprising several motor patterns, including tail flicking, foreleg waves and push ups (Peters and Ord 2003. Austral Ecol. 28:499–506). Bouts of these displays are often repeated after moving to a new location. While their displays attract the attention of conspecifics, they can also attract the attention of potential predators.

ASPIDOSCELIS COSTATA BARRANCARUM (Barranca Whiptail). **DIET**. Little is known about the diet of any of the subspecies of *Aspidoscelis costata* (*sensu* Duellman and Zweifel 1962. Bull. Am. Mus. Nat. Hist. 123:155–210; Wright 1993. *In* Wright and Vitt [eds.], Biology of Whiptail Lizards [genus *Cnemidophorus*], pp. 27–81. Oklahoma Mus. Nat. Hist., Norman, Oklahoma). We describe prey items removed from specimens of *A. costata barrancarum*, a subspecies described as *Cnemidophorus sacki barrancorum* from 28 specimens from adjacent parts of Sonora and Chihuahua, México (Zweifel 1959. Bull. Am. Mus. Nat. Hist. 117:57–116). The 14 individuals used in this study were collected by JALE in southwestern Chihuahua, México and transferred to the University of Colorado. They were then shipped to the University of Arkansas by HMS, their stomach contents were removed by JMW and identified by MAP, and they were catalogued into the Herpetological Collection of Unidad de Biología, Tecnología y Prototipos (UBIPRO) as follows: N of Batópilas at km 50.5 on Chihuahua Hwy 75 from Samachique to Batópilas (27.1149°N, 107.6646°W, WGS84; elev. 687 m, 16 June 2001 [UBIPRO 7316]; 17 June 2001 [UBIPRO 7318]); Satevo (26.9905°N, 107.7647°W, 567 m, 18 June 2001 [UBIPRO 7328–7330]); Arroyo El Camuchil (27.0261°N, 107.7625°W, 435 m, 19 June 2001 [UPIBRO 7369]); Ejido Gorojaki (27.4266°N, 108.5550°W, 450 m, 21 July 2003 [UPIBRO 11475, 11476, 11478, 11479, 11505]); Chínipas (27.3944°N, 108.5360°W, 469 m, 23 July 2003 [UPIBRO 11528, 11530, 11533]). Lemos-Espinal et al. 2003. (Herpetol. Rev. 34:365–366) provided a description of habitat in which *A. costata barrancarum* forages and engages in other activities; mean SVL of 10 gravid females was 82.7 ± 2.9 (range 67–97); mean SVL of 4 males was 101.5 ± 4.6 (range 97–104). Stomach contents were dissected from each specimen and preserved in separate vials containing 70% ethanol until analyzed. Each prey item was identified to at least order (often family) and its length and width measured to the nearest 0.1 mm to estimate prey item volume using the formula $V = 4/3\ (0.5\ \text{length}) \times (0.5\ \text{width})^2$ (Vitt et al. 2003. J. Zool. 71:2391–2400).

TABLE 1. Diet of 14 *Aspidoscelis costatus barrancarum* collected from southwestern Chihuahua, México. Arthropod orders are capitalized. Three hundred fifty-two prey items comprising 18,060 mm^3 total volume were recorded.

Prey Taxon	% by Number	% by Volume	% of Stomachs Containing
ARANEAE	4.8	6.4	35.7

PUPAE	1.7	28.3	21.4
Unidentifiable	0.9	0.1	21.4

Ants (Formicidae) were the numerically dominant prey taxon as one lizard consumed 92, a second consumed 80, and a third consumed 31 (together comprising more than half of all the prey items identified; Table 1). The dominant prey by volume were insect pupae, caterpillars (Lepidoptera larvae), beetles (Coleoptera adults), and ants. Caterpillars were the only prey taxon consumed by a majority of lizards surveyed (though ants were consumed by half the lizards). The only other study of *A. costata* diet of which we are aware, Brooks and Mitchell (1989. Southwest. Nat. 34:541–546), which was based on lizards collected from the Alamos Region of Sonora, México, reported termites as the numerically dominant prey. However, similar to our study, they found that beetles, caterpillars, and ants made up most of the volume of lizard prey consumed. Having ants constitute such a large part of the diet is unusual for a whiptail lizard (Mitchell 1979. Can. J. Zool. 57:1487–1499; Paulissen et al. 2003. Southwest. Nat. 38:377–381).

CTENOSAURA SIMILIS (Black Spiny-Tailed Iguana), ***GOPHERUS POLYPHEMUS*** (Gopher Tortoise). **CONCURRENT BURROW USE.** *Ctenosaura similis* is exotic to Florida (Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida, Krieger Publ. Co., Malabar, Florida. 155 pp.), whereas *Gopherus polyphemus* is listed as a species of special concern by the state of Florida (Florida Wildlife Code Chap. 39 F.A.C.), and as a threatened species by the Florida Committee on Rare and Endangered Plants and Animals (FCREPA) (Moler 1992. Rare and Endangered Biota of Florida: Volume III, Reptiles and Amphibians. University Press of Florida, Gainesville, Florida. 291 pp.). Three *C. similis* were introduced to Gasparilla Island (Charlotte and Lee counties) ca. 30–35 years ago, where the species is now abundant (Krysko et al. 2003. Florida Sci. 66:141–146). Among the many concerns about the high density of ctenosaurs on Gasparilla Island are their impacts to threatened and endangered species (Krysko et al. 2003. Florida Sci. 66:141–146). *C. similis* is well-known to occupy *G. polyphemus* burrows, but apparently *G. polyphemus* cohabitation has not been observed following their occupation by ctenosaurs (McKercher 2001. Unpubl. M.Sc. thesis, Univ. Florida, Gainesville, Florida. 117 pp.). We report here observations of ctenosaur usage of active *G. polyphemus* burrows and the effects on *G. polyphemus*.

From 14–28 February 2008 we made a series of observations on Gasparilla Island, Florida at a 0.1-ha site of undeveloped habitat surrounded by a neighborhood of homes with manicured landscaping. Approximately 14 adult *G. polyphemus* resided in this small area, with a similar number of adult *C. similis*. As part of an invasive species removal effort, and to avoid impacting tortoises during the invasive species removal operations, observations on burrow usage were made on 12 days during the time span.

Ctenosaurs would actively move among the burrows (created by *G. polyphemus*), appearing to purposefully investigate other burrows holding other ctenosaurs. Ctenosaurs would readily enter burrows already occupied by a tortoise (or another ctenosaur). If a tortoise was situated at the burrow entrance, an iguana would not hesitate to scramble over or around the tortoise to enter the burrow, without causing the tortoise to exit. Typically, a tortoise would readily enter a burrow already holding a ctenosaur. However, we observed that a burrow which appeared to be regularly occupied by four ctenosaurs was not observed, either directly or from tracks, to be entered by a tortoise. Once 12 *C. similis* were removed from the site (and only one or two adult *C. similis* remained on the entire site), that burrow no longer was occupied by ctenosaurs and *G. polyphemus* resumed using it. Thus, some low level of burrow sharing appears to be tolerated by *G. polyphemus*, but they also seem to be repelled from burrows at some level of *C. similis* activity.

Our observations relate only to the willingness to share burrows. Other potentially negative aspects of *C. similis* activity such as *G. polyphemus* nest destruction was not addressed. Examination of the stomach contents of *C. similis* removed from Gasparilla Island will be examined for *G. polyphemus* eggs and examination of *G. polyphemus* burrow aprons for *G. polyphemus* nests that were intentionally (e.g., predation) or accidentally (e.g., byproduct of ctenosaur nesting) disturbed or destroyed by *C. similis* will help identify other negative aspects of their activities.

CTENOSAURA SIMILIS (Black Spiny-Tailed Iguana), ***COLUBER CONSTRICTOR PRIAPUS*** (Southern Black Racer). **NON-PREDATORY KILLING.** *Ctenosaura similis* is exotic to Florida (Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida. 155 pp.). In particular, three individuals were released on Gasparilla Island (Charlotte and Lee counties) ca. 30–35 years ago, where they are now abundant (Krysko et al. 2003. Florida Sci. 66:141–146). This species may pose a threat to a number of endemic threatened and endangered species on Gasparilla Island such as eggs and young of nesting shorebirds, beach mice, hatchling sea turtles and Gopher Tortoises (*Gopherus polyphemus*) (Krysko et al., *op. cit.*). We report evidence that *C. similis* may also pose a threat to snakes.

On 10 November 2007, MK observed a ca 60 cm (total length) adult male *C. similis* attack a similarly long *Coluber constrictor priapus*. The iguana was basking on a rock at 1400 h on a warm (ca. 28°C) afternoon, when it attacked the racer as it approached within 2 m of the lizard's position. The ctenosaur rushed the snake and grabbed it in its mouth and shook it vigorously, much as dogs are prone to do. Once the snake was limp and appeared dead, the lizard dropped it and backed off 30–40 cm. When it noticed the snake's body twitching, it again rushed it and shook it, and again dropped it and backed off 30–40 cm. Further twitching of the snake's body resulted in another rush and even more vigorous shaking of the snake with the lizard backing off about 2 m this time, but additional twitching triggered another rush and shaking. Once the racer ceased to move, the iguana ignored it. The scene was observed for 20 min more to see if the ctenosaur would eat the racer, but it did not. The next morning its carcass was in the same spot.

We cannot clearly explain the ctenosaur's behavior towards the racer, but a defense mechanism towards snakes seems plausible. Janzen and Brodie (1995. J. Herpetol. 29:132–136) studied color cues in ctenosaur foraging by using different color patterns on snake replicas. They found brightly colored replica snakes (red, yellow, black) elicited the most attacks, but concluded the lizards

perceived the replicas as colored flowers or fruits because snakes were unknown in ctenosaur diet studies and snakes with such coloration could pose a hazard to the lizards (Janzen and Brodie, *op. cit.*). Our observation clearly shows the willingness of a ctenosaur to attack a snake, even though the racer most closely resembled the monotone color pattern that elicited the fewest attacks in the Janzen and Brodie study. More importantly, this behavior may have implications regarding the potential for *C. similis* to impact threatened or endangered species. If this behavior is innate in *C. similis*, juvenile *Drymarchon corais couperi* (Eastern Indigo Snakes), a threatened species (Moler 1992. Rare and Endangered Biota of Florida, Vol III, Amphibians and Reptiles. University Press of Florida, Gainesville, Florida. 291 pp.), could be severely impacted. A high-density population of *C. similis*, such as found on Gasparilla Island, could negatively affect snake recruitment through such behavior.

DIPLOLAEMUS DARWINI (NCN). **SAUROPHAGY**. *Diplolaemus darwini* is a poorly known leiosaurid lizard found in Patagonia south of 44°S latitude. Data on the diet of this species is sketchy, though some authors mention it to be insectivorous (Cei 1986. Reptiles del Centro, Centro-Oeste y Sur de la Argentina, Mus. Reg. Sci. Nat. Torino, Monogr. IV:1–527). Here we report an observation of interspecific saurophagy by an adult *D. darwini* on an adult *Liolaemus lineomaculatus*.

On 17 January 2008 during a field trip to Sierra del Bagual (49.40ºS, 71.83ºW; WGS84; elev. 601 m), Lago Argentino Department, Santa Cruz Province, southern Patagonia, Argentina; we observed an adult female *D. darwini* (92.9 mm SVL, 61.6 mm tail) basking on a rock in shrub-steppe habitat. When we chased it, the lizard ran under a rock where we captured it by hand. A few hours after we had temporarily placed this lizard in a plastic container, it regurgitated the remains of a female *L. lineomaculatus* (26.6 mm long × 12.5 mm wide). We estimated the original size of the *L. lineomaculatus* by comparison with other preserved *L. lineomaculatus* to be ca. 60 mm SVL. We also examined the remaining stomach contents of the *D. darwini* and found it to contain two tenebrionid beetles (*Nyctela* sp.). These two lizard species are synoptic in this area of Patagonian steppe and usually share similar habitats. Saurophagy has not been previously documented in the field for *D. darwini*.

D. R. Perez verified the identifications and the *D. darwini* (LJAMM 9390) and the *L. lineomaculatus* (LJAMM 7292) were deposited in the Herpetological Collection LJAMM (Luciano Javier Avila Mariana Morando) of the Centro Nacional Patagónico (CENPAT), Puerto Madryn, Chubut.

Submitted by **CRISTIAN HERNAN FULVIO PEREZ**, **NATALIA FELTRIN**, **MARIA FLORENCIA BREITMAN**, and **LUCIANO JAVIER AVILA**, CENPAT-CONICET, Boulevard Almirante Brown 2825, U9120ACF, Puerto Madryn (Chubut), Argentina (e-mail: avila@cenpat.edu.ar).

GAMBELIA COPEI (Cope's Leopard Lizard). **ENDOPARASITES.** *Gambelia copei*, a near-endemic to Baja California, ranges from extreme southern San Diego County, California, south to the northern Cape Region, Baja California Sur, Mexico (Grismer 2002. Amphibians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley, California. 399 pp.). To our knowledge, no reports of helminths exist for this species. The purpose of this note is to document the nematode *Thubunaea iguanae* from *G. copei*.

One *G. copei* female (108 mm SVL) collected in 1949 and deposited in the Natural History Museum of Los Angeles County (LACM), Los Angeles County, California, USA (LACM 4005, vic. Cerro Elefante, Vizcaino Desert, 27.2966°N, 114.3750°W, WGS84; elev. 335 m) was examined for helminths. The body cavity was opened and the coelomic cavity and visceral organs were examined. One nematode was found. It was cleared in a drop of glycerol on a glass slide, cover-slipped and identified as an adult female *T. iguanae* and deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC 101071.

Thubunaea iguanae is widely distributed among lizards from the southwestern United States and Mexico and has been reported from crotaphytids, gekkonids, phrynosomatids, teiids, and xantusiids (Telford 1965. Jpn. J. Exp. Med. 35:111–114) as well as colubrid snakes (Goldberg and Bursey 2001. Bull. South. California Acad. Sci. 100:109–116). It is in the family Physalopteridae, which utilize insect intermediate hosts (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission, 2nd ed. CABI Publishing, Oxfordshire, UK, 650 pp.). *Gambelia copei* is a new host record for *T iguanae*.

We thank Christine Thacker (LACM) for permission to examine *G. copei*.

GLAPHYROMORPHUS NIGRICAUDUS (NCN). **PREY PIRACY.** Prey piracy, the opportunistic theft of prey from another predator or another indirect source, is known for a broad range of diurnal reptilian taxa. In this note I report on an incidence of prey piracy in the skink *Glaphyromorphus nigricaudus*.

Glaphyromorphus nigricaudus is a secretive species restricted to tropical northeast Queensland, Australia. Like most of its genus, it prefers shaded moist habitats and is reported to be nocturnal-

crepuscular, but is sometimes active during the day (Cogger 2000. Reptiles and Amphibians of Australia, Reed Publishing, Sydney, Australia. 808 pp.). While conducting fieldwork at Trinity Beach in north-eastern Australia (145.6978°E, 16.7861°S; WGS84; elev. 3 m) at 1453 h EST on the 17 February 2001, I observed an adult *G. nigricaudus* patrolling 5–10 cm from a well-established Green Ant (*Oecotsylla smaragolia*) column oriented in an eastward direction. Many of the ants were transporting prey back to a nest located in a nearby tree. Over a period of 18 min, I observed the lizard lunge quickly at individual ants carrying specific prey. Following each successful lunge, the lizard would retreat a short distance from the column (20–40 cm) to consume the prey. From a nearby vantage point, I determined that the majority of prey items targeted by the lizard were lepidopteran larvae.

The cryptic nature and high diversity of Australian skinks (Cogger, *op. cit*.) implies that the frequency with which prey piracy occurs among Australian skinks may be substantially underestimated. Nonetheless, at least four other cases of skink species opportunistically stealing prey (directly or indirectly) from other predators have been reported. Three of these records involve cases of direct piracy from ant columns by the diurnal species *Carlia munda* (Bedford 1995. Herpetol. Rev. 26:99–100), *Cryptoblepharus virgatus* (Greer 1989. The Biology and Evolution of Australian Lizards. Surrey Beatty and Sons, Chipping Norton, Sydney. 264 pp.), and *Morethia boulengeri* (as *Ablepharus lineoocelatus*) (Chisholm 1923. Aust. Zool. 3:60–71). A fourth observation was the theft of arthropod prey from eumenid mud-wasp nests involving *Cryptoblepharus virgatus* (Phillips 2005. Herpetofauna 35:120). Members of the genus *Glaphyromorphus* are almost entirely terrestrial, crepuscular and secretive in habit (Greer, *op. cit*.), suggesting that high energy prey, such as lepidopteran larvae, may be only infrequently available. If this is indeed the case, instances of prey piracy, as I report here, may provide such species with an additional and energetically favorable form of prey.

Submitted by **BRETT A. GOODMAN**, James Cook University, Townsville 4811, Queensland, Australia; e-mail: brett.goodman@jcu.edu.au.

GLAPHYROMORPHUS PUNCTULATUS (NCN). **ENTRAPMENT.** At 0847 h (EST) on 22 March 2008 while observing a heliothermic skink assemblage (*Carlia rhomboidalis, Eulamprus brachysoma*) at Cape Hillsborough Nature Reserve, Queensland, Australia (20.9217°S, 149.0453°E; WGS84; elev. 10 m), we observed a small skink moving in a conspicuous hapless manner through the leaf litter substrate. The lizard was making considerable noise for an animal of its small size. Closer inspection revealed the skink to be a juvenile *G. punctulatus* with a seed casing of the fruit of the Peanut Tree (*Sterculia quadrifida*) completely enclosing the anterior portion of its head. Initial attempts to loosen and remove the seed casing failed and it appeared the casing had been on the skink's head for a couple of days and had dried to some degree, contracting over its head and neck. The thickness of the seed casing and the absence of holes (apart from the one in which the lizard inadvertently inserted its head) suggests the lizard had no ability to see while the seed casing was on its head. This was further evident by the lizard's abnormal and risk-prone activity, such as wandering through exposed areas of the open forest. As the seed casing was likely to tighten due to further drying, it seemed unlikely that the lizard would have been able extricate itself from the casing on its own, which ultimately would have resulted in the skink's death, directly or indirectly (predation). Careful work made it possible to fracture the casing along three small cracks to allow removing it from the lizard's head. After removal, the lizard was examined for injuries. Minor injury existed to the scales, presumably from rubbing contact with the seed, and minor cuts existed around the lizard's head and neck. Following removal, the lizard was weighed (to ± 0.1 g) and measured (± 0.1 mm) prior to release at the site of capture. The skink weighed 0.5 g and was 36.1 mm SVL with a total unbroken tail length of 46.7 mm. When released, the lizard moved and behaved as typical for a member of this genus. Head trapping by a plant seed casing similar to that reported here was observed in a specimen of *Lampropholis guichenoti* (Langkilde et al. 2002. Herpetofauna 32:131), implying that such entrapment might be more widespread than realized, but rarely observed in nature.

Submitted by **BRETT A. GOODMAN** (e-mail: Brett.Goodman@jcu.edu.au), **KAI I. GOODMAN, BETSY JACKES,** and **JOANNE L. ISSAC**, School of Marine and Tropical Biology, James Cook University, Townsville, Queensland, 4811, Australia.

HEMIDACTYLUS PALAICHTHUS (Spiny House Gecko). **EGG AGGREGATION**. *Hemidactylus* geckos lay clutches of only one or two eggs (Krysko et al. 2003. Amphibia-Reptilia 24:390–396; Fitch 1970. Misc. Pub. Univ. Kansas Mus. Nat. Hist. 52:1–247), but several clutches may be produced annually, greatly elevating reproductive capacity. As many as 20 clutches have been reported to be produced annually (Hernández et al. Especies Exóticas Invasoras. http://www.geocities.com/otecbio_especies/ [consulted 22 February 2006]). Further, egg aggregations (communal nesting and/or repeated use of oviposition site by single females) that locally increase the number of eggs that may offer other advantages, e.g., predator-satiation (Eckrich and Owens 1995. Herpetologica 51:349–354) or thermoregulation (Booth and Astill 2001. Austr. J. Zool., 49:71–48). Large numbers of eggs are typically interpreted as communal nesting, but larger aggregations of gecko eggs may also represent repeated use of oviposition site by individual females or some combination of both (Bock 1996. Herpetol. Rev. 27:181–183).

Large egg aggregations are known for several species of *Hemidactylus*: *H. mabouia*, 6–60 eggs (Dixon and Soini 1986. The Reptiles of the Upper Amazon Basin, Iquitos Region, Peru. Milwaukee Public Museum, Milwaukee. 154 pp.; FitzSimons 1943. The Lizards of South Africa. Transvaal Mus. Mem.,1:1–528; Krysko et al. 2005. Carib. J. Sci. 41:169–172; Rivas et al. 2005. Herpetol. Rev. 36:121–125); *H. turcicus* with up to 20 eggs (Selcer 1986. Copeia 1986:956–962); and *H. brookii* with 16 eggs (Shanbhag 1999. Herpetol. Rev. 30:166). However, we are unaware of any literature recording this or any other aspect of the reproductive biology of *H. palaichthus*.

On 2 February 2006 at 0800 h, during field work on the herpetofauna of north Amazonas, Venezuela (12 km S of Puerto Ayacucho, road to Gavilán, Estado Amazonas, Venezuela; 5.5741667°N, 67.5358333°W, datum: La Canoa; elev. ± 80 m), a pair of adult

H. palaichthus (female: 60 mm SVL; male: 65 mm SVL) were encountered inside a small abandoned doghouse. Next to these animals was 23 apparently viable eggs. Shell fragments of two other eggs that had already hatched and one older-appearing damaged egg were also found. Eight eggs from the aggregation contained embryos in the final stages of development (evident from shell translucency and intense pigmentation of the embryos). The remaining 15 eggs had white or light pink shells and lacked distinguishable embryos. Additionally, we found an apparent recent hatchling (26 mm SVL) next to the nest.

The nest was located on the ground, in a narrow space (ca. 1 cm) under a cement brick inside the dog-house. The eggs were surrounded by scattered leaf litter and the remains of a plastic bag. Air temperature in the nest was of 28.9°C and relative humidity was 76%.

Presence of an adult pair (male and female) near the nest, and the absence of other females nearby, may indicate that this site is repeatedly used by this female rather than as a communal nest (i.e., at least two females). The large number of eggs may also indicate a high annual fecundity. Bock (*op. cit.*) established (in *H. mabouia*) that aggregations of up to 10 incubating eggs likely result from both communal nesting and repeated use of the same site by individual females; additional observation would be needed to identify the basis of the large number of eggs we found. Finally, the finding of shells of only two eggs suggests that *H. palaichthus* eggs tend to hatch in pairs, implying that the female lays both eggs of a single clutch simultaneously.

The geckos were released after taking measurements and photographs. J. Celsa Señaris verified the species identification. We gratefully acknowledge funding provided by the National Science Foundation (grant no. DEB-0416160) to Eric N. Smith. We also thank Gabriel Ugueto for suggestions on this note.

HOPLOCERCUS SPINOSUS (NCN). **ENDOPARASITES.** *Hoplocercus spinosus* is a poorly known lizard distributed from the Mato Grosso and Mato Grosso do Sul region of Brazil to adjacent Bolivia (Wiens and Etheridge 2003. Herpetologica 59:375–398). To our knowledge, no parasite records have been published for *H. spinosus*. Hence, here we report the presence of *Cruzia rudolphii* in *H. spinosus.*

We examined 5 adult *H. spinosus* (mean = 80.4 mm SVL, ± 12.3 mm SD) deposited in the Coleção Zoológica de Referência, Laboratory of Zoology, Campus of Corumbá, Universidade Federal de Mato Grosso do Sul (UFMS) (CEUCH 2888, 2892, 3374, 3375, and 3460) for endoparasites. Lizards were captured in November 2003 and February 2004 in pitfall traps with drift fences in a remnant fragment of Cerradão (forest savanna-like vegetation) of Dois Irmãos do Buriti and Terenos (55.30ºW, 20.50ºS; WGS84; elev. 300 m) between the municipality of Aquidauna and Campo Grande, Mato Grosso do Sul, Brazil. Lizards were euthanized and the body cavity, esophagus, stomach, lungs, small and large intestines were opened and separately examined for helminths under a stereomicroscope. Endoparasites were cleared in phenol, identified and deposited in the Coleção Helmintológica do Instituto de Biociências da Unesp de Botucatu as *C. rudolphii* (CHIBB 1052). Three adult females of *C. rudolphii* were recovered and the observed prevalence (infected lizards/examined lizards × 100) was 20%.

Species of *Cruzia* have been reported in many taxa, such as mammals (Quintão e Silva and Costa 1999. J. Wildl. Dis. 35:371–374) and reptiles (Vicente et al. 1993. Rev. Bras. Zool. 10:1–183). *Cruzia rudolphii* was originally described from the colubrid snake *Erythrolamprus aesculapii* in southeastern Brazil (Ruiz 1947 in Vicente et al. 1993, *op. cit.*). *Hoplocercus spinosus* represents a new host record for *C. rudolphii* and Mato Grosso do Sul, Brazil is a new locality for the parasite.

We thank M. Hayes for comments on the manuscript. This study had financial support by FAPESP (processes 04/03628-1; 06/59692-5) and RWA thanks CAPES for a grant.

LEIOCEPHALUS CARINATUS ARMOURI (Northern Curlytail Lizard). **MORTALITY.** *Leiocephalus carinatus armouri* is a well established, exotic species in Florida (Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida. 155 pp.; Meshaka et al. 2005. Southeast. Nat. 4:521–526; Smith and Engeman 2004a. Florida Field Nat. 32:107–113); but few causes of mortality, including vertebrate predators, have been documented within its introduced range (Smith and Engeman 2003. Herpetol. Rev. 34:245–246; Smith and Engeman 2004a. *op cit.*; Smith and Engeman 2004b. Herpetol. Rev. 35:169–170; Dean et al. 2005. Herpetol. Rev. 36:451; Smith et al. 2006a. Herpetol. Rev. 37:224). Only surface paving (Smith and Engeman 2004a, *op. cit.*), vehicle-related road-kill (Smith et al. 2006b. Herpetol. Rev. 37:87), and entanglement in persistent human-made debris (Dean et al. 2005. Herpetol. Rev. 36:179–180) have been reported as abiotic sources of mortality. Here, we quantify extensive mortality to an entire *L. c. armouri* colony resulting from parking lot sealing and repaving.

At ca. 1300 h on 10 July 2006, surface sealing and repaving of a parking area off Woolbright Road was initiated at the location of a colony of *L. c. armouri* in Boynton Beach, Florida (see Smith and Engeman 2003, *op. cit.*; Smith and Engeman 2004a, *op. cit.* for site descriptions of this colony). On the two previous days (8–9 July), a total of 81 active *L. c. armouri* burrows had been located

within the proposed work area. As with standard Gopher Tortoise (*Gopherus polyphemus*) surveys (Cox et al. 1987. Ecology and Habitat Protection Needs of Gopher Tortoise [*Gopherus polyphemus*] Populations on Lands Slated for Large-scale Development in Florida. Nongame Wildlife Program Tech. Rept. No. 4, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida), active lizard burrows were similarly identified by fresh dirt piled outside their entrances, and tail drags and/or lizard footprints entering them. Lizards were also observed fleeing into several burrows during the survey. The 10 July repaving work affected the entire south side of the study area colony, which contained 43 active burrows. On the morning of 11 July, 39 of these 43 burrows (91%) were either flooded with liquid sealer/tar or had the substance at least partially extending into the burrow entrance. No lizards were observed at the entrances, or around, these 39 burrows. The 4 unimpacted burrows appeared active. Repaving continued throughout 11 July to include the additional south and east areas, and on 12 July the colony was resurveyed. The 12 July survey revealed that 45 of 51 burrows (88%) in those areas were now entombed. The 4 active burrows found on 11 July were still active for a total of 6 active burrows in those areas. Surveys were not conducted on the mornings of 13–14 July, but by 15 July, the north side of the colony had now been repaved. A survey on that morning revealed 56 of 65 burrows (86%) entombed. Nine burrows were active, including the 6 found on 11 and 12 July. By Sunday 16 July, the treatment had been completed on the west side of the colony and 71 of the 81 burrows (88%) were now entombed, and ten were active. Additional construction and curb painting at the site on 18 July forced an end to all surveys when most burrow markers were lost.

Burrow collapse and entombment of animals is recognized as a factor in animal mortality by off-road vehicle use (Brock and Kelt 2004. Biol. Cons. 118:633–640; Luckenbach and Bury 1983. J. Appl. Ecol. 20:265–286). While entombment of burrowing animals during road construction or repaving may be acknowledged as a cause of animal mortality in many environmental assessments, impact statements, and federal rulings (USFWS 2000. Federal Register 65:57242–57264.; USFWS 2003. Federal Register 68:13498–13520.), the actual numbers of animals in an impacted area are frequently unknown.

Biotic factors impacting exotic herpetofauna populations (e.g.; predation, disease, parasites) are often described in the literature (see extensive species accounts in Meshaka et al. 2004, *op. cit.*). However, abiotic sources of mortality for exotic herpetofauna remain poorly known, or underreported, especially at the colony-site or deme level. Meshaka et al. (2005, *op. cit*.) noted that for some invasive species such as *L. c. armouri*, which utilizes heavily human-modified coastal habitat to provide "**…**open sunny conditions and cement analogues to the rocky substratum to which it is adapted," abiotic mortality factors may likewise be more of a limiting factor to exotic populations than biotic factors.

LEIOCEPHALUS CARINATUS ARMOURI (Northern Curly-tail Lizard). **PREDATION.** Although several avian predators are documented (Smith and Engeman 2004a. Herpetol. Rev. 35:169–170; Smith et al. 2006a. Herpetol. Rev. 37:224; Smith et al. 2006b. J. Kansas Herpetol. 19:9), virtually nothing is known about the mammalian predators and scavengers of *Leiocephalus carinatus armouri* within its introduced range in Florida. To date, only one mammalian predator, feral cat (*Felis catus*) (Smith and Engeman 2004b. Florida Field Nat. 32:107–113), and one mammalian scavenger, Gray Squirrel (*Sciurus carolinensis*; Smith et al. 2006c. Herpetol. Rev. 37:87) have been verified. Here we report the predation of a juvenile *L. c. armouri* by a second mammalian predator in Florida, the domestic dog (*Canis familiaris*).

At 1435 h on 17 December 2006 (a warm [ca.75°F] sunny day), HTS observed an unleashed ca. 10-kg mixed-breed dog chase a juvenile (ca. 5 cm SVL) *L. c. armouri* through the south side of the Woolbright Road colony of *L. c. armouri* located in Boynton Beach, Florida (see previous site descriptions in Smith and Engeman 2003. Herpetol. Rev. 34:245–246; Smith and Engeman 2004b, *op. cit.*). The chase was a rapid, straight-line run of about 10 m with the dog gaining ground. The *L. c. armouri* reached the south wall of a building, could not find its burrow entry quickly enough, and was captured in the dog's jaws. The dog then thoroughly macerated the lizard for 30–45 sec before swallowing it.

Feral cats were frequent predators of *L. c. armouri* at this colony (Smith and Engeman 2004b, *op. cit.*) from 1993 until property management changed in 2005 at which time free-living feral cats were aggressively removed, and pet dogs were allowed to condominium residents. Observations of domestic dogs preying on other iguanid lizard species have been reported (Iverson 1978. Biol. Conserv. 14:63–73; Henderson 1992. Carib. J. Sci. 28:1–10). The effects of domestic dog predation on *L. c. armouri* colony population dynamics and recruitment are unknown.

LEIOCEPHALUS PSAMMODROMUS (Turks and Caicos Curly-Tailed Lizard). **CONSPECIFIC NECROPHAGY**. At 1200 h on 6 December 2007 on Big Ambergris Cay in the Turks and Caicos Islands (21.299°N, 71.633°W; elev. 11 m), I documented a young adult female *Leiocephalus psammodromus* (ca. 60 mm SVL) feeding on the carcass of a road-killed adult male conspecific (ca. 85 mm SVL). The condition of the carcass, considerably flattened and dried out, indicated that the male was likely recently killed by construction traffic and repeatedly run over. The observation, which lasted 4 min, was made at a distance of 4 m from the carcass, which lay on the side of a small dirt road. During this time, the female tilted her head sideways and down to take quick bites of the carcass, rapidly returning to a vigilant head-up position to swallow small pieces. I observed a total of six feeding motions during the observation period, which ended when another male entered the area and the female retreated.

Little has been reported on the diet of *L. psammodromus*, though it has been assumed to resemble that of other members of the genus in the Bahamian Archipelago. Other *Leiocephalus* species have been reported to feed on hymenopterans, lepidopteran larvae, coleopterans, blattarians, a substantial amount of plant matter such as fruits and buds, as well as demonstrate heterospecific saurophagy (Schoener et al. 1982. Oecologia 53:160–169) and cannibalism (Jenssen et al. 1989. Anim. Behav. 38:1054–1061), but conspecific necrophagy was previously unreported in this genus. *Leiocephalus* are known to have highly opportunistic food habits (Schoener et al., *op. cit*.), and recently deceased conspecifics may provide an easily accessible source of protein for young adults of this species.

I thank the Turks and Caicos Sporting Club at Ambergris Cay for logistical support and M. Hayes for suggestions. Financial support provided by the Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville.

Submitted by **R. GRAHAM REYNOLDS**, Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996, USA; e-mail: rgraham@utk.edu.

LEIOSAURUS BELLI (NCN). **PREDATION**. Birds are often reported to prey on lizards (e.g., Pérez and Avila. 2005. Herpetol. Rev. 36:451–452; Terres 1991. The Audubon Society Encyclopedia of North American Birds. Wing Books, New York, New York, USA. 1109 pp.; Trejo et al. 2003. Herpetol. Rev. 34:145), but such predation events typically occur rapidly so that the field observation of the event is rarely recorded. Hence, we report an observation of White-throated Cacholote (*Pseudoseisura gutturalis*) preying on *Leiosaurus belli* from southeast Argentina.

Observations were made near Puerto Madryn, Biedma Department, Chubut province (42.34ºS, 64.09ºW, WGS84; elev. 20 m) using 8 × 30 binoculars. At ca. 1315 h on 23 October 2007, CHFP observed an adult male *P. gutturalis* arriving at the nest carrying remains of the hind leg of *L. belli* in its bill. Within 5 min, both members of the pair brought the remainder of the tail. Both birds hesitated briefly before entering the nest to feed the nestlings, presumably due to the presence of the observer close to the nest (less than 3 m). This allowed identification of the lizard and photography. Based on photographs of the leg, the size of the *L. belli* was estimated to be ca. 85 mm SVL. The nest contained four nestlings about 8 days old weighing 31–46 g.

Leiosaurus belli is a moderate-sized (<100 mm SVL) diurnal and relatively aggressive lizard inhabiting shrubby areas in Monte and Patagonian steppe of the Mendoza, Neuquén, La Pampa, Río Negro and Chubut provinces, Argentina (Cei 1986. Museo Regionale di Scienze Naturali Torino, Monographie 4:1–528). The only a report of its bird predators is based on remains found in pellets (Udrizar Sauthier et al. 2007. Herpetol. Rev. 38:78–79). The White-thoated Cacholote is an active diurnal bird weighing 63–79 g, endemic to the Monte and Patagonia steppes in Argentina (Remsen 2003. *In* del Hoyo et al. [eds.], Handbook of the Birds of the World, vol 8, pp. 162–357. Lynx Edicions, Barcelona, Spain). To date, small vertebrates were not known to be part of the diet of the White-throated Cacholote or any other member of the genus *Pseudoseisura*, which are regarded as predators primarily on invertebrates (Remsen, *op. cit*.).

Submitted by **CRISTIAN HERNAN FULVIO PEREZ,** CENPAT-CONICET, Boulevard Almirante Brown 2825, U9120ACF, Puerto Madryn, Chubut, Argentina (e-mail: liolaemus@cenpat.edu.ar); **KASPAR DELHEY,** Vogelwarte Radolfzell, Max Planck Institute for Ornithology Schlossallee 2, D-78315, Germany; **PABLO F. PETRACCI,** Cátedra Zoología III Vertebrados, Facultad de Ciencias Naturales and Museo de La Plata, Paseo del Bosque s/n, 1900 La Plata, Buenos Aires, Argentina; and **LUCIANO JAVIER AVILA**, CENPAT-CONICET, Boulevard Almirante Brown 2825, U9120ACF, Puerto Madryn, Chubut, Argentina (e-mail: avila@cenpat.edu.ar).

LIOLAEMUS ROTHI (NCN). **CANNIBALISM**. *Liolaemus rothi* is a stout, medium-sized liolaemid lizard found in northern Patagonia (Neuquén, Río Negro, and Chubut provinces) in steppe or steppe-Monte ecotone habitats on rocky substrates. Though some authors mention it to be insectivorous, dietary data are scarce (Cei 1986. Reptiles del Centro, Centro-Oeste y Sur de la Argentina, Monogr. IV, Mus. Reg. Sci. Nat. Torino, Italy. 527 pp.). Here, we report an observation of intraspecific saurophagy in *L. rothi*.

Around 1100 h on 20 February 2008, during an ecological study of this species at a location 20 km N of Gan Gan (42.4071°S, 68.2634°W; datum: WGS84; elev. 1071 m), Departamento Telsen, Chubut, Argentina, we observed and filmed (for 3 min) an adult (81 mm SVL) male *L. rothi* eating a conspecific juvenile. When first observed, the adult was swallowing the juvenile. Only the hindlimbs and tail of the juvenile were visible, but enough features could be observed for accurate identification.

In the genus *Liolaemus*, cannibalism has been only reported for *L. darwinii* (Ripoll and Acosta 2007. Herpetol. Rev. 38:459). The causes of this behavior in liolaemid lizards merit investigation.

Submitted by **MONICA KOZYKARISKI** (e-mail: kozykariski@cenpat.edu.ar), **JONATHAN GOLDMAN, MELISA OLAVE**, and **LUCIANO JAVIER ÁVILA** (e-mail: avila@cenpat.edu.ar), CENPAT-CONICET. Boulevard Brown 2825, U9120ACF, Puerto Madryn, Chubut, Argentina.

OPHIODES FRAGILIS (Cobra-de-Vidro). **CANNIBALISM**. *Ophiodes fragilis*, a medium-sized anguid (228 mm max SVL) distributed in southern and southeastern Brazil and northeastern Argentina (Misiones Province), inhabits forested areas (Borges-Martins 1998. Unpubl. Ph.D. dissertation. Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, Rio Grande do Sul, Brazil. 239 pp.). Though anguids are generally recognized as carnivorous and are known to feed on insects, small mammals, other lizards, and molluscs (Smith 1946. Handbook of Lizards. Comstock Publ. Associates, Ithaca, New York. 557 pp.; Pough et al. 2001. Herpetology, 2nd ed. Prentice Hall, Upper Saddle River, New Jersey. 612 pp.; Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. University of California Press, Berkeley, California. 333 pp.), little is known about the diet of *O. fragilis*. The only existing dietary study recorded only small arthropods (Marques and Sazima 2004. *In* Marques and Duleba [eds.], Estação Ecológica Juréia-Itatins: Ambiente Físico, Flora e Fauna, pp.

257–277. Editora Holos, Ribeirão Preto, São Paulo, Brazil.). Here, we report the first record of cannibalism in *O. fragilis.*

In January 1994, Ivan Rubens Brum found an already dead adult male *O. fragilis* (184 mm SVL), at Canela, Rio Grande do Sul, Brazil (29.3638°S, 50.8100°W; WGS84; elev. 835 m), that contained four almost undigested conspecific juveniles (110 mm total length).

The adult male *O. fragilis* (MCP 5987) and juveniles (MCPAN 1856) it had eaten were deposited in the collection of Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul.

PHELSUMA MADAGASCARIENESIS GRANDIS (Madagascar Day Gecko). **PREY**. *Phelsuma madagascarienesis grandis* is native to northern Madagascar (Henkel and Schmidt 2000. Amphibians and Reptiles of Madagascar and the Mascarene, Seychelles, and the Comoro Islands. Krieger Publ. Co., Malabar, Florida. 319 pp.) and has been introduced into the United States in Hawaii (Kraus 2002. Bishop Mus. Occ. Pap. 69:48–52) and Florida (Krysko et al. 2003. Florida Sci. 66:222–225). *Phelsuma m. grandis* is diurnal and arboreal, and feeds primarily on nectar, pollen and arthropods (Krysko et al., *op. cit.*; Krysko and Hooper 2007. Gekko 5:33–38; Tytle 1992. Vivarium 2:15–19, 29), but adults occasionally eat hatchling *Phelsuma* (Krysko et al., *op. cit.*) and *Hemidactylus* geckos (García and Vences 2002. Herpetol. Rev. 33:53–54; Krysko and Hooper, *op. cit.*). Herein, we report *P. m. grandis* preying upon the nonindigenous Northern Curly-tailed Lizard (*Leiocephalus carinatus*) in Florida.

At 1420 h on 30 August 2008, an adult male *Phelsuma m. grandis* was observed in Lake Worth, Palm Beach County (26.625634°N, -80.05083°W, WGS84, elev. <1 m) on a building wall. Upon closer examination, the gecko was holding a neonate (ca. 30 mm SVL) *Leiocephalus carinatus* in its mouth. After being photographed (photographic voucher UF 153515) the gecko retreated into a stand of *Heliconia* sp., and ca. 1 h later the gecko reemerged and appeared fat. This is the first record of *Phelsuma m. grandis* consuming *Leiocephalus carinatus*, and the first record of this gecko in Palm Beach County, Florida.

Submitted by **CARL D. MAY**, 1311 N Lakeside Drive, Lake Worth, Florida 33460, USA; and **KENNETH L. KRYSKO**, Florida Museum of Natural History, Division of Herpetology, P.O. Box 117800, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu).

PHRYNOSOMA CORNUTUM (Texas Horned Lizard). **NESTING; HATCHLING BEHAVIOR; PREDATION**. At 1245 h CDT on 3 June 2008, we observed a young female (37.6 g; ca. 65 mm SVL) *Phrynosoma cornutum* digging a first nest in caliche soil in Randall County, Texas (vicinity of 34.98°N, 101.93°W, NAD27; elev. 1080 m). The nest was completed by 1100 h on 4 June on a 9.5° slope facing SW. The lizard weighed 20.7 g after oviposition, having lost 44.9% of her pre-oviposition weight (similar to reports by Allison and Cepeda (2009. Southwest. Nat. 54[2]: *in press*) and Sherbrooke 2002. Herpetol. Rev. 33:206–208). Twenty-four hatchlings (of 25 total eggs recovered from excavating the nest on 18 August) emerged between 2000 h on 6 August and 1400 h on 7 August from one exit hole 3 cm × 2 cm. We weighed 14 of the hatchlings (mean = 0.71 g, ± 0.11 SD), and variation in mass was similar to that reported by Sherbrooke (2002).

Emerging hatchlings were more alert and active than those we have previously observed from other nests. At times, several hatchlings waited to emerge from the nest, climbing over one another to exit. One ate tiny ants (<4 mm) before and while exiting the nest opening. Several hatchlings were seen sand-diving at the exit or immediately after exiting the nest, or when dispersing further when a threat was perceived. At 1136 h on 7 August, a Blue Jay (*Cyanocitta cristata*) flew low to the ground over the nest site. At 1148 h, the jay landed at the site and a hatchling that had just emerged immediately crouched at the approach of the bird. The crouching hatchling was snatched up by the jay, and 3 other hatchlings inside the exit hole immediately froze. The jay wrestled the first hatchling in its beak for 10 sec, and manipulated the now apparently dead hatchling into its beak over the next 12 sec. The other 3 hatchlings remained motionless. With the first hatchling still in its beak, the jay stood out of sight of the remaining hatchlings, appeared to listen for activity inside the nest and, within 3 sec, snatched a second hatchling head-first from within the exit hole. The 2 hatchlings left at the exit hole remained motionless.

At the time of the predation episode, 18 hatchlings had emerged, and 10 hatchlings were within 2 m of the nest site. A period of sunshine during a mostly cloudy morning may have initiated a period of greater hatchling activity that caught the attention of the jay. In contrast to the hatchlings freezing at the jay's approach, our arrival at the nest caused one hatchling to dive back into the nest and the other to bury itself inside the exit hole.

Lizards were weighed, measured, and immediately released in accordance with permit SPR-0294-659 issued by the Texas Parks and Wildlife Department.

Submitted by **PAMELA S. ALLISON**, P.O. Box 60812, Canyon, Texas 79016, USA (e-mail: psallison@earthlink.net); and **JOSEPH C. CEPEDA**, West Texas A&M University, Department of Life, Earth, and Environmental Science, P.O. Box 60938, Canyon, Texas 79016 (e-mail: jcepeda@mail.wtamu.edu).

SPHENOMORPHUS CHERRIEI (Striped Litter Skink, Chirbala Lisa). **ENDOPARASITES.** *Sphenomorphus cherriei* is a litter-dwelling skink known from central Veracruz, México to extreme western Panama (Savage 2002. The Amphibians and Reptiles of Costa Rica; A Herpetofauna Between Two Continents Between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). To our knowledge, only one report of endoparasites for *S. cherriei* exists;

Goldberg and Bursey (2007. Herpetol. Rev. 38:83–84) reported one species of Digenea *Mesocoelium monas* and three species of Nematoda *Oswaldocruzia nicaraguensis*, *Physaloptera* sp., and acuariid larvae.

The coelomic cavity of one mature female *S. cherriei* (64 mm SVL) from the herpetological collection of the Natural History Museum of Los Angeles County (LACM 162570) collected in Puntarenas Province, Costa Rica (9.22246°N, 83.84309°W, WGS84; elev. 50 m) in 1973 was examined for helminths. The body cavity was opened and the visceral organs examined under a dissecting microscope. One larva was found encysted in the liver. It was excised, cleared in a drop of undiluted glycerol on a glass slide, examined under a compound microscope and assigned to the genus *Porrocaecum*. The larva was deposited in the United States National Parasite Collection, Beltsville, Maryland as USNPC 100569.

Adults of *Porrocaecum* live in the intestines of birds; eggs pass with the feces and are eaten by earthworms in which they hatch (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission, 2nd Ed. CABI Publishing, Oxfordshire, UK, 650 pp.). Vermivorous vertebrates may act as paratenic (= transport) hosts; larvae mature when ingested by an appropriate host (Anderson, *op. cit.). Sphenomorphus cherriei* represents a new paratenic host record for *Porrocaecum* sp. and can be added to the list of poikilothermic Costa Rican vertebrates serving as paratenic hosts in Goldberg and Bursey (2008. Herpetol. Rev. 39:350).

We thank Christine Thacker (LACM) for permission to examine the *S. cherriei* that is part of the CRE collection donated in 1998 by Jay M. Savage.

TILIQUA ADELAIDENSIS (Pygmy Bluetongue Lizard). **MATING BEHAVIOR.** *Tiliqua adelaidensis* is an endangered scincid lizard found exclusively in remnant fragments of native grassland habitat in mid-north South Australia (Armstrong et al. 1993. Rec. S. Austral. Mus. 36:53–55; Hutchinson et al. 1994. Trans. Roy. Soc. Ser. A. 118:217–226). The smallest member of the genus *Tiliqua* (adult SVL ca. 95 mm), males have shorter body lengths and longer, wider heads than females (Hutchinson et al., *op. cit.*). The lizards live in burrows constructed by lycosid and mygalomorph spiders, which they use for both shelter and vantage points for ambushing passing prey (Milne et al 2003. Wildl. Res. 30:523–528). Mating occurs in late October to early November and 2–4 live young are born in late January to mid March (Hutchinson et al., *op. cit.*; Milne et al., *op. cit.*).

Milne et al (*op. cit.*) video-recorded burrow entrances and filmed one episode of mating where a male entered a female burrow and dragged her from the burrow by her head. At the surface, the lizards rolled vigorously until the male eventually grasped the female, and proceeded to mate, copulation lasting 30 sec. The female then entered her burrow and the male remained at the burrow entrance for 30 min, making occasional attempts to pull the female out again. During another study that involved filming the behavior of wild *T. adelaidensis* on closed circuit video cameras (CCTV), we recorded a second mating event that differed from the first observation by Milne et al (*op. cit.*). The purpose of this note is to detail these observations.

At 1000 h on 11 November 2007, we were recording a adult (ca. 85 mm SVL) male *T. adelaidensis* at his burrow entrance. The view frame for the camera was about 1 m^2. A adult (ca. 85 mm SVL) female entered the frame of view and within 5 sec the male had left his burrow and grasped the female on the left shoulder with his jaws. The male appeared to try and subdue the female who was attempting to escape the grasp of the male. The initial struggle lasted 35 sec, until the male managed to move his body on top of the female, while vigorously waving his rear left leg as if trying to raise the female tail. By this time, the female was in a 'C' position with the male on top, also in a 'C' position over her. The male eventually raised the tail of the female and aligned his cloaca with hers. He appeared to lock the female tail between his tail and body to hold his position for 37 sec while mating. The male maintained his grasp of the female shoulder throughout the mating. The female started struggling vigorously towards the end of the mating and the male eventually released his grasp. The entire mating sequence lasted 77 sec. Both the male and female then ran into the male burrow where they remained. After 10.5 min, a second adult (ca. 90 mm SVL) male lizard entered the frame of view from the same direction as the female had. This male tongue flicked about 20 times as it moved towards the burrow. At 1012 h, this male partially (to mid-body) entered into the burrow and the posterior part of its body could be seen thrashing around. The second male then emerged, dragging the female out of the burrow with him, grasping her by the left rear leg. When she was completely outside the burrow, he flung her to one side, briefly releasing his grip. She sat motionless near the burrow entrance for 5 sec before moving rapidly away in the opposite direction from where she had come and away from the burrow. The second male re-entered the burrow after 5 sec and remained completely inside the burrow for 70 sec before re-emerging. He then circled once around the burrow tongue flicking about 38 times in 30 seconds, before re-entering the burrow for a third time. He emerged once more after 10 sec, and slowly (50 sec to move 50 cm) left the area in the same direction he had come, tongue flicking 16 times on the way. The original male emerged from the burrow after another 70 sec and basked at the burrow entrance with his head and forearms exposed. Seventy-six min later, the second male (or one of similar size and appearance) returned to the burrow. The first male retreated into the burrow followed by the second male, who remained in the burrow for 15 sec. The second male then emerged and left the frame 20 sec later. After another 15 sec, the first male emerged and continued to bask as before. No further interactions were observed over the 3 h of filming.

Though the copulation time of ca. 30 sec was similar to that reported by Milne et al (*op. cit.*), our observation of mating differed in one major aspect. In the former episode, a male initiated mating by entering a burrow occupied by a female. Here, the first male was at his burrow entrance and seized a passing female. The second male behaved in a manner similar to the episode described by Milne et al. (*op. cit.*), though no mating occurred. However, the appearance of a second male in the current observation implies that

pheromone trailing or some other olfactory cue may be being left by receptive females. Our observation also suggests that at least two mating strategies exist for *T. adelaidensis*, the first more selective (when a male approaches a female) and the second more opportunistic. However, both observations suggest that females have little choice in mate selection. Understanding the mating behavior of threatened species is crucial, as it enables better management and conservation strategies to be developed, particularly for captive breeding programs and translocations and reintroductions.

TUPINAMBIS MERIANAE (White Tegu), ***TUPINAMBIS TEGUIXIN*** (Golden Tegu). **PREDATION ON SNAKES.** Lizards of the genus *Tupinambis* are omnivores; their diet includes invertebrates, vertebrates, eggs, and diverse fruits (Presch 1973. Copeia 1973[4]:740–746; Sazima and Haddad 1992. *In* L.P.C. Morellato (ed.), Répteis da Serra do Japi: Notas Sobre a História Natural, pp. 212–235. Unicamp/FAPES: Campinas, SP, Brazil). These diurnally active lizards are known to be ophiophagous, but few data exist on the species of snakes upon which they feed. Here, we report two events of predation by *Tupinambis* where the snakes were identified from the Brazilian Pantanal and southern Brazil.

At 1252 h on 22 September 2006, we observed an adult *Tupinambis merianae* near a small lake on a restinga located on the coastal plain of the State of Santa Catarina, southern Brazil (27.83°S, 48.62°W; elev. 5 m). The tegu was regurgitating its stomach contents and fled quickly upon our approach. In the stomach contents we found remains of plants, insects, and an intact adult male *Sordellina punctata* (total length of 30 cm). We deposited the *S. punctata* in the herpetological collection of the Universidade Federal de Santa Catarina (CHUFSC) (Kunz et al. 2007. Biotemas 20:127–132).

At 1310 h on 27 November 2007, we observed an adult *T. teguixin* preying on an adult *Leptophis ahaetulla* (ca. 1 m TL), on the shore of the Vermelho River, Pantanal, State of Mato Grosso do Sul (19.60°S, 56.90°W; elev. 200 m). We observed the event for 98 sec. During this period, the *T. teguixin* caught and bit the snake ca. 30 cm from the end of its tail. The *T. teguixin* had a short struggle with its prey, which tried to bite the tegu three times. After this, the lizard left rapidly with the snake in its mouth.

Our data indicate that both *Tupinambis* species have the ability to subdue aglyphous adult snakes with semi-aquatic (*S. punctata*) and arboreal habits (*L. ahaetulla*).

OLIVEIRA-SANTOS**, Universidade Federal do Mato Grosso do Sul - UFMS, Programa de Pós-Graduação em Ecologia e Conservação, Centro de Ciências Biológicas e da Saúde, CEP 79070-900 Campo Grande, MS, Brazil (e-mail: gu_tapirus@hotmail.com); and **CAROLINE LEUCHTENBERGER**, Laboratório de Vida Selvagem, Embrapa Pantanal, Rua 21 de Setembro, 1880, Bairro Nossa Senhora de Fátima, Caixa Postal 109, Corumbá, MS, Brazil 79320-900 (e-mail: caroleucht@gmail.com).

VARANUS VARIUS (Lace Monitor). **PREDATION**. *Varanus varius*, Australia's largest lizard based on mass, is widespread over eastern continental Australia and selected offshore islands (Cogger 2000. Reptiles and Amphibians of Australia, 6th ed.. Reed New Holland, Frenchs Forest, Australia. 808 pp.). A large terrestrial and arboreal carnivore taking a broad range of prey, *V. varius* is similar to most varanids in being regarded as strictly diurnal (Cogger, *op. cit*.). Here we report a nocturnal observation of arboreal predation by *V. varius* on an adult Common Brushtail Possum, *Trichosurus vulpecula*.

On two occasions between 3 and 17 January 2008, JR observed a very large *V. varius* (ca. 1 m SVL, ca. 30 cm across the dorsum at widest point) active by day foraging and scavenging food scraps left by campers at Tathra Beach Motor Village, Andy Poole Drive, a caravan park located ca. 1 km N of Tathra, on the south coast of New South Wales, Australia. This individual, likely a female, is a well-known long-term resident of the area recognizable from a cataract in its left eye; this animal has often been observed in previous years during the holiday season. A population of *T. vulpecula* were also locally resident, and their noisy vocalizations and movements across roofs of cabins and recreational vehicles were frequently heard at all times of the night. At ~0030 h (EST) on 13 December 2007 (a warm, humid, and starlit but moonless night), JR heard the typical *T. vulpecula* advertisement call, but it soon changed to a loud alarm call. When JR looked out through cabin window, he observed the aforementioned *V. varius* in a ~6 m high *Eucalyptus* sp. tree (36.71829°S, 149.97608°E; WGS84; elev. 1 m) located ~6 m E of the cabin. The *V. varius* was situated on a major lateral branch above the main fork of the trunk, which was ~4.5 m above the ground at the base of the canopy, with an adult *T. vulpecula* situated among foliage at the end of the same branch. At this point, JR went to retrieve a camera with a nightscope function (Panasonic Lumix™), during which time the alarm call was abruptly cut off. Upon his return, JR observed the *V. varius* through the camera with the *T. vulpecula* in its mouth, in the process of swallowing it, a process completed in ~5 min. Whether the lizard was actively hunting, or had opportunistically seized the *T. vulpecula* while resting in the tree when the latter was moving about is unknown. Habitat consisted of an open cleared area with several permanent cabins and scattered *Eucalyptus* trees (either remnant or planted), located adjacent to a remnant ~20 m-wide strip of dense coastal heath/dry sclerophyll woodland. This strip of woodland was located on the west side of a paved road, which had another ~40 m wide strip of similar woodland on its east side behind the edge of the beach. The eastern edge of this camping area was located ~150 m inland from the high tide mark.

Varanus varius is a diurnal predator on a wide range of reptiles, birds, and mammals, including *T. vulpecula* captured by day in tree-hollow refugia and is a well-known scavenger of roadkills, farm animal mortalities, and food scraps left by humans (Cogger, *op. cit.*; DM, pers. obs.), but predation at night has been hitherto unreported. More observations will be needed to determine whether noctural predation by *V. varius* represents an active hunting strategy.

We thank M. Hayes for editorial suggestions.

XENOSAURUS PHALAROANTHEREON (NCN). **DIET**. Few data exist on the feeding habits of knob-scaled lizards (genus *Xenosaurus*). Lemos-Espinal et al. (2003. Southwest. Nat. 48:119–122) indicated that *Xenosaurus grandis*, *X. platyceps*, and *X. newmanorum* consume primarily insects, though they found remains of a mammal in one *X. newmanorum*. Here, we report a second instance of mammal predation among xenosaurine lizards.

On 16 May 2004, we captured an adult (102.7 mm SVL) male *Xenosaurus phalaroanthereon* 6.1 km SW by road of San Juan Acaltepec, (16.2478°N, 95.9607°W, WGS84; elev. 2160 m) the type locality of this species in the Sierra Madre del Sur, Oaxaca, México. We obtained a fecal sample and released the animal at the point of capture. Using the technique of Arita and Aranda (1987. Técnicas para el Estudio y Clasificación de los Pelos. Inst. Nal. de Inv. Sobre Rec. Bióticos, Xalapa Veracruz. 21 pp.) and data from Baca (2002. Catálogo de Pelos de Guardia Dorsal en Mamíferos Terrestres del Estado de Oaxaca, México. México D.F. 100 pp.), we identified hair from the fecal sample as belonging to an unidentified species of harvest mouse (genus *Reithrodontomys*).

We cannot distinguish whether the mouse eaten was the result of the lizard capturing a live animal or scavenging a dead one. As the only small mammal previously reported is from the diet of *X. newmanorum* (Lemos-Espinal et al. 2003, *op. cit.*) and no other dietary data exist for *X. phalaroanthereon* (Lemos-Espinal and Smith 2005. Phyllomedusa 4:133–137), more information on *X. phalaroanthereon* diet will be necessary to properly evaluate our observation.

SERPENTES — SNAKES

AGKISTRODON PISCIVORUS LEUCOSTOMA (Western Cottonmouth). **DIET**. *Agkistrodon piscivorus leucostoma* eats a wide variety of prey including rodents, birds, bird eggs, snakes, frogs, and numerous species of fish (Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History, University of Texas Press, Austin, Texas. 437 pp.). We add a new species of lizard to this list. On 14 September 2006, a recently killed juvenile *A. p. leucostoma* (239.0 mm SVL, 289.0 mm TL, 13.1 g; TNHC 67394) was turned in to the San Angelo Nature Center from a residence on the shores of Lake Nasworthy, Tom Green County, Texas. Although the snake was beheaded, both the body and head were vouchered. Upon further examination, the snake's stomach contained a juvenile *Sceloporus olivaceus* (48.0 mm SVL, 113.0 mm TL, 3.42 g; cataloged separately as TNHC 67395), swallowed headfirst.

Submitted by **MICHAEL S. PRICE,** San Angelo Nature Center, 7409 Knickerbocker Road, San Angelo, Texas 76904, USA (e-mail: michael.price@sanangelotexas.us); and **TRAVIS J. LADUC**, Texas Natural History Collections, Texas Natural Science Center, The University of Texas at Austin, 10100 N. Burnet Road, PRC 176-R4000, Austin, Texas 78758-4445, USA (e-mail: travieso@mail.utexas.edu).

BOGERTOPHIS SUBOCULARIS (Trans-Pecos Ratsnake). **ARBOREALITY.** *Bogertophis subocularis* inhabits the Chihuahuan Desert of west Texas, New Mexico, and northern Mexico (Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. University of Texas Press, Austin). Within this region, it is known to occupy subterranean and terrestrial habitats with most field-collected specimens found amongst rocky slopes and outcrops (Werler and Dixon, *op. cit.*). Although these snakes are known to be adept climbers in rocky habitat, similar climbing activity has not been reported from arboreal settings. Here we report on two observations of arboreal activity in this species.

On 1 July 2007, we observed two male *B. subocularis* at approximately 1378 m elevation in Box Canyon, Sierra Vieja, Presidio County, Texas. The first (790 mm SVL, 920 mm TL, 146 g) was found at 0005 h crawling amongst the outer branches of an *Acacia greggii* (Catclaw Acacia) ca. 1.75 m above the ground. This acacia was one of several in a bunch ca. 2 m from the edge of a dry wash (30.5501°N, 104.6592°W). Twenty minutes later and ca. 150 m from the first snake, we found a second *B. subocularis* (724 mm SVL, 839 mm TL, 112 g) crawling down a ca. 10 cm diameter branch of a *Quercus emoryi* (Emory Oak) ca. 4 m above the ground. The *Q. emoryi* is near the confluence of Box Canyon and Fox Hollow (30.5498°N, 104.6588°W) and equidistant (ca. 4 m) from the edge of each wash. Although previous authors note that most *B. subocularis* are active between sunset and midnight on nights with little moonlight (Tennant 1984. The Snakes of Texas. Texas Monthly Press, Austin; Werler and Dixon, *op. cit.*), these two individuals were observed after midnight during the full moon. Additionally, the snake found in the oak tree was parasitized by a single tick, which we presume was *Aponomma elaphensis*, whose only known host is *B. subocularis* (Degenhardt and Degenhardt 1965. Southwest. Nat. 10:167–178).

We thank the Miller family for supporting and encouraging biological research on their ranch.

BOIGA SIAMENSIS (Grey Cat Snake). **DIET**. Pauwels et al. (2005. Russ. J. Herpetol. 12:102–106), recently placed *Boiga ocellata* (Grey Cat Snake) in the synonymy *Boiga siamensis*. The species is known from Bangladesh, northeast India (westwards up to Bengal), Myanmar, Thailand, Cambodia, Laos, and Vietnam (Orlov and Ryabov 2002. Russ. J. Herpetol. 10:217–240; Teynié et al. 2004. Hamadryad 29:33–62; Stuart and Emmett 2006. Fieldiana Zool. new ser. 109:1–27; Teynié and David 2007. Russ. J. Herpetol. 14:39–44). *Boiga siamensis* is known to consume birds and their eggs (Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Peninsular Malaysia, Singapore and Thailand. Ralph

Curtis Publishing, Inc., Sanibel Island, Florida).

On 23 May 2004 at ca. 1940 h we found a *B. siamensis* (1600 mm total length) attempting to consume a *Acridotheres tristis* (Common Myna) within the branches of a *Leucaena leucocephala* (White Popinac) behind the research house in Huay Khayenk Village (14.607889ºN, 98.582167ºE), Huay Khayenk Subdistrict, Thong Pha Phum District, Kanchanaburi Province, Thailand. The snake bit the bird at the wing and tried to kill it by constricting it. At ca. 2000 h the snake was disturbed and it released the bird. The snake was photographed and released.

We thank G. Vogel for assistance.

BOTHROPS ASPER (Fer-de-lance)**. DEFENSIVE BEHAVIOR.** *Bothrops asper* is an abundant pitviper widespread throughout much of Central America (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York), and is the species responsible for most snakebite fatalities in the region (Hardy 1994. Biotropica 26:198–207; Saborío et al. 1998. Toxicon 36:359–366). However, published accounts of the circumstances surrounding such snakebites are rare, and the majority of such cases occur when the snake is accidentally grabbed or trod upon (Hardy 1994. Herpetol. Nat. Hist. 2:67–82). Here we report a case of defensive behavior by an unmolested adult *B. asper* at La Selva Biological Station, Puerto Viejo de Sarapiquí, Herédia Province, Costa Rica (10.4313°N, 84.0036°W).

At 2110 h on 6 March 2005, we were radiotracking *B. asper* and encountered a non-telemetered female (1.7 m total length). The animal was moving slowly through undergrowth when encountered and showed no obvious response when cautiously approached to a distance of ca. 2.5 m. After being quietly observed for about 3 min and continuing to move away, the snake suddenly recoiled as if startled, although no stimulus was observed. It immediately turned 180˚ and began to advance rapidly with the head slightly raised towards us, causing us to quickly retreat. The snake proceeded to follow the exact nonlinear retreat path of one of us (JBL) for ca. 4 m, at which point it stopped, lowered its head, and did not immediately retreat but after ca. 30 sec resumed gradual slow movement in its original direction of travel. This sequence appeared similar to the "type I offensive advance" described for elapids (Whitaker and Shine 1999. Wildl. Res. 26:689–704).

Although the species is often depicted in popular literature and folklore as highly prone to unprovoked aggression, no similar reactions or attempted strikes were witnessed by DKW over more than 4500 similar observations of adult *B. asper*. A nocturnal ambush predator, fer-de-lance tended to flee in response to human approach at night, and usually displayed no visible reaction at all during the day, relying instead on crypsis. The present case seems atypical in that the snake was neither handled nor restrained, stimuli which can elicit defensive behavior in other pitvipers that otherwise appear similarly hesitant to strike (Gibbons and Dorcas 2002. Copeia 2002:195–198; Prior and Weatherhead 1994. J. Herpetol. 28:255–257). Factors influencing the described event remain unclear, although the fact that the snake was moving when encountered should be considered.

LOSOS**, Museum of Comparative Zoology and Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, Massachusetts 02138, USA (e-mail: JLosos@oeb.harvard.edu).

BOTHROPS ASPER (Terciopelo). **DIET**. *Bothrops asper* occupy an important position in the food chain of tropical ecosystems. At Los Tuxtlas region (Veracruz, Mexico) adult *B. asper* feed on medium to large food items such as rodents (*Rattus* sp., *Didelphis* sp.), small birds, and juvenile conspecifics, whereas juveniles feed on smaller prey such as anurans (*Craugastor rhodopis*, *Smilisca baudini*), lizards (*Ameiva undulata*), and arthropods (Buttenhoff and Vogt 1997. *In* Gonzáles-Soriano et al. [eds.], Historia Natural de Región se Los Tuxtlas, pp. 478–480. Universidad Nacional Autónoma de México, Districto Federal, México; Pérez-Higareda et al. 2007. Serpientes de la Región de Los Tuxtlas, Veracruz, México. Universidad Nacional Autónoma de México, D.F., México). Herein I report the first record of *B. asper* eating a *Lepidophyma tuxtlae* (Tuxtla Tropical Night Lizard).

On 12 April 2005 at 2210 h, I found at Los Tuxtlas rainforest (18.53°N, 95.1°W) two subadult of *B. asper* approximately one meter apart and 20 m from the forest edge. One of these individuals fled but the other (ca. 835 mm SVL) had a half-swallowed *L. tuxtlae* (ca. 73 mm SVL) in its mouth. A color photographic voucher (MZFC-ID 1603) has been deposited in the herpetological collection of Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México.

I thank V. H. Reynoso and U. O. García-Vazquez for assistance.

Submitted by **J. NICOLÁS URBINA-CARDONA,** Museo de Zoología, Departamento de Biología Evolutiva, Facultad de Ciencias, Universidad Nacional Autónoma de México, A.P. 70-399 C.P. 04510. México DF; e-mail: nurbina@yahoo.com.

CARPHOPHIS AMOENUS HELENEA (Midwest Worm Snake). **DEFENSIVE BEHAVIOR**. Very little is known about the defensive behaviors of small fossorial snakes, including *Carphophis amoenus*. Most noted behaviors, other than escaping, include prodding with the pointed tail-tip and a flattened body posture with a partially buried head under coils (Clark 1970. Univ. Kansas Publ. Mus. Nat. Hist. 19:85–194).

On 10 May 2007 at Beech Fork State Park in Wayne County, West Virginia (38.28488°N, 082.41875°W), a non-gravid female *C. amoenus* was found under a large dome shaped rock. After handling the specimen, it was placed on the ground and proceeded to remain still in a loosely coiled pattern with its head partially buried under part of its body. The tail was positioned on top of the coils and the tail-tip oriented vertically as if it were mimicking the head. The tail tip remained motionless, as did the rest of the main

body, for the duration of the time photographed after which it was replaced under the cover object. This is the first report of a worm snake species exhibiting this type of defensive behavior.

Submitted by **ERIC H. DIEFENBACHER (**e-mail: eric.diefenbacher@gmail.com) and **THOMAS K. PAULEY** (e-mail: pauley@marshall.edu), Department of Biological Sciences, Marshall University, Huntington, West Virginia 25755, USA.

CORONELLA AUSTRIACA (Smooth Snake). **PARAPHIMOSIS.** Paraphimosis is a common condition in captive reptiles (Bennet 1996. *In* Mader [ed.], Reptile Medicine and Surgery, pp. 355–357. W.B. Saunders Co., Philadelphia, Pennsylvania) and occurs as a result of inflammation of the hemipenis, or hemipenes, making retraction through the cloaca impossible (DeNardo 1996. *In* Mader, *op. cit*., pp. 212–224). Although common in captivity, this condition has not, to our knowledge, been recorded in a wild snake. Here, we report a wild *Coronella austriaca* showing clinical signs of paraphimosis.

On 10 August 2006 at 1159 h an adult male *C. austriaca* (433 mm SVL, 138 mm tail length [TL], 42 g) was captured at a lowland heath site in Dorset, United Kingdom. While collecting morphometric data as part of an ongoing mark-recapture study, we noticed that the blackened and necrotic left hemipenis was extruding from the cloaca (Fig. 1). The snake was in an otherwise healthy condition and showed no outward signs of any secondary infection that commonly accompany physical traumas (Cooper and Jackson 1981. Diseases of the Reptilia, Academic Press, London). The snake had been previously captured on 31 May 2006 (433 mm SVL, 138 mm TL, 45 g) when paraphimosis was not evident. The animal was released at the point of capture following data collection and subsequently recaptured on 2 August 2007 at 0957 h near the original locality. The necrotic mass was absent and there was minimal scar tissue present at the scales surrounding the cloaca. The snake was in a healthy condition (471 mm SVL, 140 mm TL, 54 g) and was again released at the point of capture.

FIG. 1. Lateral and ventral views of a necrotic prolapsed hemipenis observed on a wild *Coronella austriaca*.

The most common injuries observed in *C. austriaca* are physical traumas and damage to tails (Cooper and Davies 1997. Herpetol. J. 7:19–22), which can reduce survival and predispose individuals to infection (Cooper and Jackson, *op. cit*.). Paraphimosis did not appear to produce secondary infection in this instance and is unlikely to prevent the individual from reproducing, since the reproductive organs on each side of the body are morphologically and functionally separate. Contralateral hemipenis use in successive reproductive events has been observed in both kingsnakes (*Lampropeltis getula*; Zweifel 1997. J. Herpetol. 31:459–461) and gartersnakes (*Thamnophis sirtalis*; Shine et al. 2000. Behav. Ecol. 11:411–415) which, if present in *C. austriaca*, may place individuals such as this at a competitive disadvantage in future breeding seasons.

CROTALUS SCUTULATUS SCUTULATUS (Mojave Rattlesnake). **DEFENSIVE BEHAVIOR/SALTATION AND HEAD HIDING**. Head hiding/coiling defensive behavior has not been previously documented in *Crotalus scutulatus scutulatus*. On 21 April 1994, several unusual behaviors were exhibited by an adult male *C. s. scutulatus* ca. 850–900 mm SVL (snout–vent length) in Fenner Valley, San Bernardino County, California, USA. At 0840 h (air temperature 27°C), a resting, fully coiled, slightly buried, adult male was observed in a gravelly wash, partially shaded by a large shrub (Fig.1A). After I took numerous photos from different compass directions, the snake remained motionless until it struck at me without rattling or moving into an aggressive striking position, and became airborne. The snake struck directly at me from the position facing 90° to my left (Fig.1A), a distance greater than its full body length. As the snake struck, it came completely off the ground (at least 15–20 cm) and propelled itself forward landing between my feet. A similar type of saltation behavior was

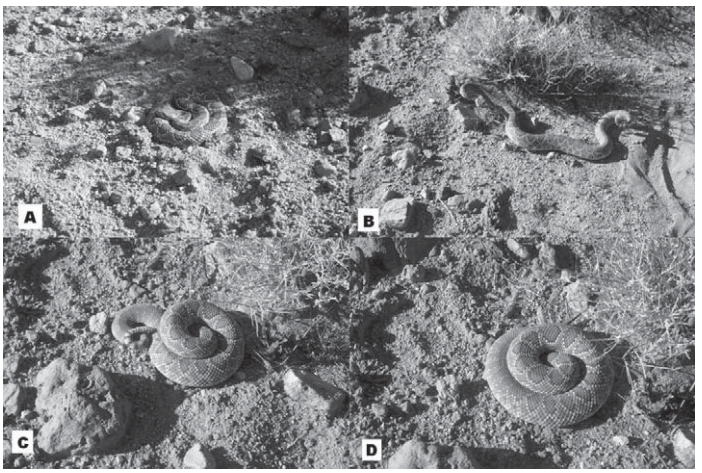

FIG. 1. Male Mojave Rattlesnake (*Crotalus s. scutulatus*) behavioral sequence of head-hiding: A) resting coil; B) saltation and aggressive behavior; C) head hidden and coiling; D) coiling completed, rattle extended upward but not vibrating.

described by Bartholomew and Nohavec (1995. Great Basin Nat. 55:282–283) in reference to flight behavior of a *C. s. scutulatus* from Mohave County, Arizona. Additionally, this type of saltation behavior has been observed in *C. scutulatus salvini* (Armstrong and Murphy 1979. The Natural History of Mexican Rattlesnakes. Univ. Kansas Mus, Nat. Hist., Spec. Publ. No. 5. 88 pp.): "This rattlesnake is one of the most aggressive species we encountered. Several struck so violently that their entire body appeared to be momentarily air borne." The present observation parallels that of Armstrong and Murphy (1979, *op. cit.*). In my observations of hundreds of active rattlesnakes, the distance they could strike is about 2/3 of its body length; B. H. Brattstrom (pers. comm.) corroborated this estimate as well. Klauber (1982. Rattlesnakes. Their Habits, Life Histories, and Influence on Mankind. Abridged edition, p. 93. University of California Press, Berkeley, California) stated: "A rattler can strike only a short distance from its resting coil—only the distance involved in straightening the S-shaped section of the neck;" and Klauber (*op. cit.*) p. 96. "From my own experience I should say that a rattler will rarely strike more than half its length, measured from the front of the anchor coil, and almost never beyond three-quarters of that length." Mattison (1996. Rattler! A Natural History of Rattlesnakes. Sterling Publ. Co. Inc., New York. 144 pp.) notes "A rattler's strike is rapid—about 2–3 m (6–10 ft) per second—and can reach a distance of about half its body length. The strike is sometimes so violent that its whole body slides forward and, under exceptional circumstances, it may completely leave the ground." This particular male Mojave Rattlesnake did not follow the distance axioms estimated above.

Following the active saltation display, the snake became agitated and began body bridging, looping coils, rattling violently, and repeatedly striking in any direction as I tried to lift it with a stick to move it to a safe location. Most rattlesnakes are easily picked up near midbody with a stick and balance themselves well so they can safely be moved. This particular snake would not stay balanced on the stick and repeatedly fell off and continued to act aggressively, striking and rattling violently (Fig. 1B). This aggressive behavior continued for several minutes, with each attempt to pick up the snake eliciting continued striking, thrashing, and falling to the ground. On my final attempt to pick up the rattlesnake it began to display an unusual coiling behavior, placing its head on the ground and initiating a clockwise coiling motion on top of its head (Figs. 1D, 1E). In this position the snake's head was on the ground and completely buried under the center of its coils with the rattle erect and not vibrating. The snake stayed motionless in this position for approximately 5 minutes. Then I reached out with the stick to pick the snake up and attempt to move it again, this time the snake became docile while I moved it to a nearby wash 100 m west and released it next to a rodent burrow, into which it rapidly crawled.

A second head-hiding observation was made on 18 May 1999 of a smaller *C. s. scutulatus* (female ca. 650–700 mm SVL) in Piute Valley, Clark County, Nevada, USA. I attempted to move this snake from where I had set up some equipment. The snake repeatedly fell off the stick with which I had attempted to move it and was not striking violently as described earlier. After a number of attempts to move this snake it behaved similarly to the male specimen and hid its head (Fig. 2A), attempted to coil its body over the head, though not quite concealing it as well as the male specimen described earlier (Fig. 2B).

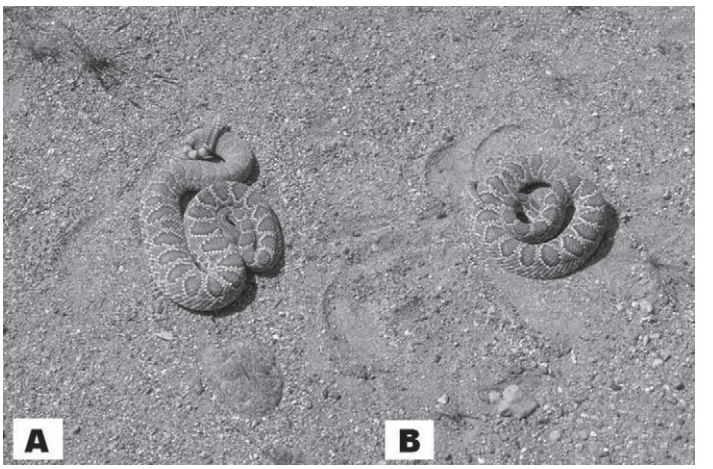

FIG. 2. Female Mojave Rattlesnake (*Crotalus s. scutulatus*) behavioral sequence of head-hiding: A) initiating head-hiding behavior; B) coiling completed, rattle silent.

Head hiding in rattlesnakes is apparently uncommon and was not documented in Carpenter and Ferguson (1977. *In* C. Gans and D. W. Tinkle [ed.], Biology of the Reptilia Vol. 7. pp. 335–554. Academic Press, New York). Subsequently, several instances of head hiding have been recorded as a result of human or predator interaction with rattlesnakes. An account of intimidation of a Western Diamondback Rattlesnake (*Crotalus atrox*) was reported (Cowles 1977. Desert Journal: A Naturalist Reflects on Arid California. Univ. California Press, Berkeley. 263 pp.) where several snakes were individually intimidated by placing a flattened hand into the face making the snake lower its head and hiding it under a coil. This behavior apparently is an attempt to avoid an attacker by escaping and to protect its head from imminent danger. A slightly different posture of head hiding behavior has been documented in *C. atrox* as an escape from predation after being confronted by a Roadrunner (*Geococcyx californianus*). After the snake struck numerous times at a Roadrunner and became exhausted, it protected its head by tucking it under its coils (Cornett 2001. The Roadrunner. Nature Trails Press, Palm Springs, California. 64 pp.; Meinzer 1993. The Roadrunner. Texas Tech Univ. Press, Lubbock, Texas. 104 pp.; Sherbrooke and Westphal 2006. Southwest Nat. 51:41–47). Head-hiding behavior has also been documented in the Prairie Rattlesnake (*Crotalus viridis viridis*) in response to human interaction (Duval et al. 1985. Nat. Geogr. Res. 1:80–111; Alcock 1998. Animal Behavior: an Evolutionary Approach. Sinauer Associates, Inc. Sunderland, Massachusetts. 640 pp.); and in the Red Diamond Rattlesnake (*Crotalus ruber*) by Rubio 1998. Rattlesnake: Portrait of a Predator. Smithsonian Institution Press, Washington, D.C. 240 pp.). Head-hiding behavior in conjunction with defensive tail displays is widespread in snakes (Greene 1973. J. Herpetol. 7:143–161). The significance of head hiding behavior in rattlesnakes and lack of rattle vibration appear to simply be a defensive measure to protect the snake and its head from human intimidation and/or possible predation.

Thanks to B. Brattstrom, M. Brattstrom, T. Esque, and K. Phillips for suggestions on this manuscript, and K. Drake and K. Nolte for preparing the figures.

DINODON RUFOZONATUM RUFOZONATUM (Asian King Snake). **DIET AND BEHAVIOR**. *Dinodon rufozonatum rufozonatum* occurs in parts of eastern China, Korea, Japan (Szczerbak 2003. Guide to the Reptiles of the Eastern Palearctic. Krieger Publishing Company, Florida. 260 pp.) and Taiwan (Lue et al. 2002. The Transition World – Guidebook of Amphibians and Reptiles of Taiwan. Swan, Taipei. 350 pp. [In Chinese]). Previously reported prey include: a chick, *Bufo bankorensis*, *Bufo melanostictus*, *Rana adenopleura*, skinks, snakes, and a beetle (Lee and Lue 1996. Biol. Bull. Natl. Taiwan Normal University 31:119–124. [In Chinese]; Lee and Lue 1996. J. Taiwan Mus. 49:137–138; Lin et al. 1995. Newsletter of Wildlifers 3:19–21 [In Chinese]; Norval and Mao 2004. Herpetol. Rev. 35:65; JJM, unpubl. obs.).

On the evening of 21 September 2007, an adult male *D. r. rufozonatum* (775 mm SVL, 169 mm tail length [TL], 198.8 g) was observed on a branch, ca. 2 m above the ground, overhanging a small concrete reservoir on the edge of a secondary forest in Santzepu, Sheishan District, Chiayi County, Taiwan (23.43ºN, 120.48ºE, WGS84). Our presence disturbed the snake and as it tried to flee it was captured. After it was measured we released it at the capture site. On 27 January 2008 at 2212 h, another adult male *D. r. rufozonatum* (729 mm SVL, 207 mm TL, 186.2 g) was observed at the reservoir, but this time on the reservoir wall. Again, our presence disturbed the snake and it tried to seek shelter under a fallen palm leaf that was lying on the wall. Numerous *Rhacophorus moltrechti* were calling from inside the reservoir, and there were some bubble-foam nests on the inside of the reservoir wall, as well as on the coconut palm leaf. The snake was captured and it was noted it had an enlarged abdominal region. After gentle palpation of the stomach region, the snake regurgitated two intact *R. moltrechti* (male: 50 mm SVL, 5.1 g; female: 56 mm SVL, 8.1 g) and ova, as well as an unidentifiable anuran (5.9 g) that was in an advanced digested state. In July 1997 in one night, we encountered several frogs and five *D. r. rufozonatum* in a large concrete reservoir in Donhe Dsitrict, Taitung County. We believe that *D. r. rufozonatum* have learned that these reservoirs provide a reliable food resource when *R. moltrechti* are breeding. To our knowledge this is the first report of *D. r. rufozonatum* predation on *R. moltrechti*.

DRYMARCHON COUPERI (Eastern Indigo Snake). **NESTING HABITAT AND EGG DEPREDATION.** Little is known about the nesting ecology of *Drymarchon couperi* in the wild. In southern Georgia, *D. couperi* females are known to lay eggs from May through early June (Moulis 1976. Bull. New York Herpetol. Soc. 12:14–23; R. Moulis, pers. comm., 2006), but there is scant information detailing where the eggs are laid. In this note, we report the discovery of a *D. couperi* nest found in southern Georgia, USA.

On 3 June 2003, one of us (SLN) found a *D. couperi* nest (N = 10 eggs) near an active, adult *Gopherus polyphemus* (Gopher Tortoise) burrow in xeric sandhill habitat, Telfair County, Georgia. Evidently, the nest had recently been excavated and depredated (in part) by a predator when discovered. The shells of four *D. couperi* eggs that had been consumed by the predator, as well as three intact eggs, were found on the sandy surface of the tortoise burrow apron. Three additional intact eggs were found in the nest cavity, which was located ca. 10 cm deep in the sand beneath and beside a rotten *Quercus laevis* (Turkey Oak) log; numerous fresh *Procyon lotor* (raccoon) tracks were observed on the burrow apron. The intact *D. couperi* eggs (N = 6) were subsequently incubated in captivity where they all hatched on 3 October 2003 . We believe that SLN or his dog may have disturbed or frightened away the nest predator (probably a raccoon) before it had time to consume the entire clutch.

The few other published observations of *D. couperi* nests also suggest that *G. polyphemus* burrows are important sites for oviposition. In southern Georgia, a *D. couperi* that had been implanted with a radio transmitter and then released nested ca. 1 month later (N = 6 eggs; between 23–29 May) in an inactive tortoise burrow (burrow width = 12.7 cm) located in an open *Pinus elliottii* (Slash Pine) plantation (Speake et al. 1978. *In* Odum and Landers [eds.], Proc. Rare and Endangered Wildlife Symposium, pp. 64–73. Georgia Dept. Nat. Res., Game and Fish Tech. Bull. WL4, Atlanta). Smith (1987. Unpubl. master's thesis. Auburn University, Auburn, Alabama. 129 pp.) reported that three radio-transmittered gravid female *D. couperi* translocated to sandhill habitat on St. Marks NWR, Wakulla County, Florida, laid eggs in tortoise burrows soon after release. The discovery of a *D. couperi* eggshell on the apron of an active tortoise burrow in southern Georgia is also circumstantial evidence that tortoise burrows or burrow aprons are used by nesting *D. couperi* (Williamson and Moulis 1979. Survey of Reptiles and Amphibians on Fort Stewart and Hunter Army Airfield. Rept. to United States Army, Fort Stewart, Georgia. 343 pp.).

Our observation bolsters the limited available information regarding *D. couperi* nesting habitat and strongly suggests that raccoons may sometimes depredate nests. A possible risk for *D. couperi* nesting inside or immediately nearby an active *G. polyphemus* burrow would be disturbance or damage to the eggs by the digging activities or regular movements of the resident tortoise. Conversely, *D. couperi*, a federally threatened species, may benefit in its apparent nesting relationship with Gopher Tortoises and their burrows by virtue of having readily available refuges and recovery shelters for post-nesting adult females, as well as for the vulnerable hatchlings.

We thank N. Hyslop for assistance.

EUNECTES MURINUS (Green Anaconda). **DIET**. *Eunectes murinus* is known to prey on a variety of species, including capybaras, white-tailed deer, and spectacled caiman as well as smaller anacondas (Rivas 1999. Life History of the Green Anaconda [*Eunectes murinus*] with Emphasis on its Reproductive Biology. Ph.D. dissertation. University of Tennesee at Knoxville. 235 pp.; Rivas and Owens 2000. Herpetol. Rev. 31:45–4).

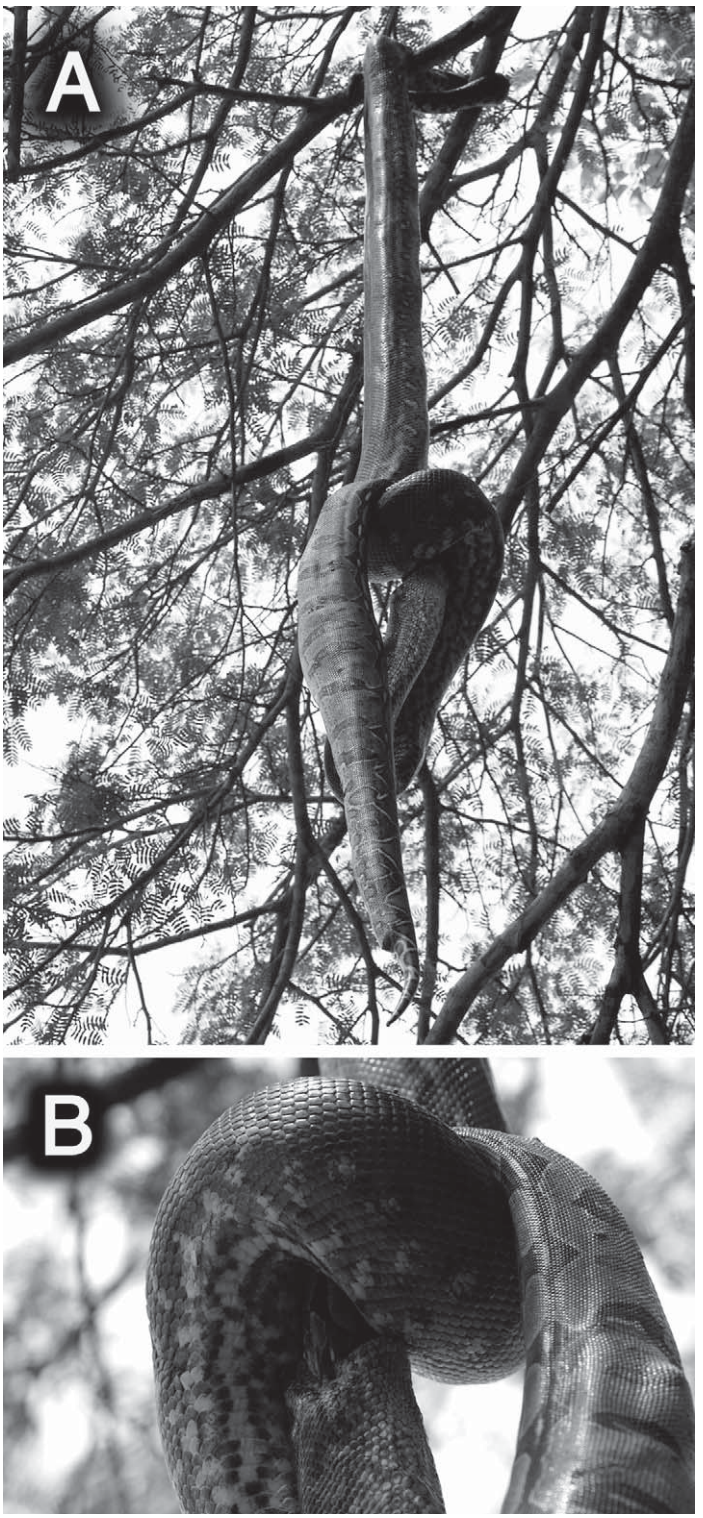

FIG. 1. A) Green Anaconda (*Eunectes murinus*) devouring Boa Constrictor (*Boa constrictor*) in gallery forest canopy. B) Close-up showing a bulge in the boa's body from a recently-ingested Green Iguana (*Iguana iguana*).

In this note we report an observation made on 16 July 2006 of a large *E. murinus* (ca. 5 m total length) attempting to eat an adult *Boa constrictor* in the South Rupununi savannas of Guyana about 7 km N of Dadanawa Ranch (2.88°N, 59.53°W). From a boat on the Rupununi River, we spotted a large adult *E. murinus* hanging by its tail from the canopy of a tree in the gallery forest ca. 5 m above the river (Fig. 1A). The anaconda had partially ingested an adult *Boa constrictor* head-first, and was supporting its prey by doubling it over a coil in the anaconda's body (Fig. 1B). After 10 minutes of observation from a distance, we approached more closely, whereupon the anaconda attempted to regurgitate its prey, first by shaking the boa from its mouth and then by wrapping its coils behind its head to forcibly push its prey loose. After 15 minutes, the anaconda dropped the boa into the river and retreated up into the canopy.

We recovered the dead boa (1.78 m total length) from the river and it had the tail of a Green Iguana (*Iguana iguana*) protruding from its mouth. The anaconda likely encountered the boa in the tree while it was in the process of digesting the recent kill and in a vulnerable condition. It is interesting that the observation was made at the height of the rainy season when it is rare to spot anacondas.

Submitted by **DUANE DE FREITAS**, Dadanawa Ranch, South Rupununi, Region #9, Essequibo, Guyana, South America; e-mail: defreitasduane@yahoo.com.

LAMPROPELTIS CALLIGASTER CALLIGASTER (Prairie Kingsnake). **DIET**. *Geomys bursarius ozarkensis* (Ozark Pocket Gopher) is an endemic that has only been reported in two counties in Arkansas (Elrod et al. 2000. J. Mammal. 81:852–864). Ozark Pocket Gophers maintain a closed underground burrow system and are rarely seen above ground. They inhabit pastureland, which is also favorable habitat for *Lampropeltis calligaster calligaster* (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp).

On 16 May 2007 at 1530 h, we discovered that a male *G. b. ozarkensis* (186 mm body length, 43.7 mm tail length, 84 g) that we were radiotracking had been consumed by a male *L. c. calligaster* (890 mm SVL, 298 g). The snake was ca. 1 m from the gopher's burrow system in a hay field off County Road 3 (36.0236°N, 91.9150°W) in Izard County, Arkansas. We did not observe the snake feeding, thus we do not know whether the snake preyed on the pocket gopher inside its burrow or above ground. The snake regurgitated the gopher and radio transmitter in captivity, ca. 3 hours later. Although small mammals, including *Geomys* sp., are common prey for *L. calligaster* (Ernst and Ernst 2003. Snakes of the United States and Canada, Smithsonian Books, Washington, DC. 668 pp; Fitch 1999. A Kansas Snake Community: Composition and Changes Over 50 Years, Krieger Publ. Co., Malabar, Florida. 165 pp; Trauth and McAllister 1995. Proc. Arkansas Acad. Sci.49:188–192), to the best of our knowledge *G. bursarius* has never been recorded in its diet.

Submitted by **MATTHEW B. CONNIOR** (e-mail: matthew.connior@smail.astate.edu), **IDUN GUENTHER**, and **THOMAS S. RISCH**, Department of Biological Sciences, Arkansas State University, State University, Arkansas 72467, USA.

LEPTODEIRA SEPTENTRIONALIS (Cat-eyed snake). **DIET.** *Leptodeira septentrionalis* is widely distributed in the Americas. It is found at low and moderate elevations on the Atlantic and Pacific slopes from southern Texas and Sinaloa, south to Peru (Lee 1996. The Amphibians and Reptiles of the Yucatan Peninsula. Comstock Publishing Associates, Cornell University Press, Ithaca, New York).

On 21 July 2006 at 2109 h we observed a juvenile *Leptodeira septentrionalis polysticta* (247 mm SVL, 323 mm total length) on a plant on low vegetation, swallowing a female Leaf Litter Frog, *Craugastor* cf. *loki* (ca. 36 mm SVL). These observations took place in a tropical rainforest fragment (6.6 ha) at Los Tuxtlas, Veracruz, Mexico (18.5953°N, 95.1208ºW, 433 m elev., WGS84). The snake was collected after feeding and deposited in Colección Nacional de Anfibios y Reptiles, Instituto de Biología, Universidad Nacional Autónoma de México (CNAR-IBH 21139).

Leptodeira septentrionalis consumes a broad range of anurans (and anuran eggs) and hunts on the ground, in low vegetation, in trees, and in water (Duellman 1963. Univ. Kansas Publ. Mus. Nat. Hist. 15:205–249; Henderson and Hoevers 1977. Copeia 1977:349–355; Lee, *op. cit*.; Pérez-Higareda et al. 2007. Serpientes de la Región de Los Tuxtlas, Veracruz, México. Guía de Identificación Ilustrada. Universidad Nacional Autónoma de México, Mexico City; Schmidt and Andrews 1936. Field. Mus. Nat. Hist. Publ. Zool. Ser. 20:167–187; Stuart 1948. Misc. Publ. Mus. Zool. Univ. Michigan 69:109). This is the first record of *Craugastor* in the diet of *L. septentrionalis*. Frogs of the genus *Craugastor* are the most abundant amphibian species living on leaf litter at Los Tuxtlas.

C.P. 04510 (e-mail: anfisbenido@yahoo.com).

LIOPHIS POECILOGYRUS (Yellow-bellied Liophis). **DIET**. *Liophis poecilogyrus* is a widely distributed colubrid snake found in South America (Dixon 1989. Smithson. Herpetol. Infor. Serv. 79:1–40). Its diet includes amphibians, lizards, insects, fishes, and rodents (Achaval and Olmos 2003. Anfíbios y Reptiles del Uruguay. 2nd ed. Graphis Impresora, Montevideo, Uruguay, 136 pp.). On 15 April 2007 at 1745 h a young *L. poecilogyrus* (220 mm SVL, 40 mm tail length) was found under a branch at the border of a lake in Campo Belo do Sul municipality, Santa Catarina State, Brazil (27.5651ºS, 50.4128ºW, 972 m elev., SAD 69). After a few minutes of handling for photographs, it regurgitated a partially ingested anuran, the semi-fossorial *Elachistocleis ovalis* (Common Oval Frog). The anuran was collected and the snake liberated after photographs.

LYCODON RUHSTRATI RUHSTRATI (Mountain Wolf Snake). **ENDOPARASITES**. The pentastomid *Raillietiella orientalis* naturally occurs in Taiwan and has been recorded as an endoparasite of *Amphiesma stolatum*, *Bungarus multicinctus multicinctus*, *Deinagkistrodon acutus*, *Elaphe carinata*, *Elaphe taeniura friesei*, *Naja atra*, *Protobothrops mucrosquamatus*, and *Ptyas mucosa* (Kuo 1999. Helminths and Pentastomids of Snakes in Taiwan. Master's thesis, Veterinary School, National Chung Hsing University, Taichung [in Chinese]).

On 18 February 2006 at 1038 h a DOR *Lycodon ruhstrati ruhstrati* (626 mm SVL, 153 mm tail length [TL], 46.3 g prior to dissection) was found on a road in Santzepu, Sheishan District, Chiayi County (23.43ºN, 120.48ºE, WGS84). On 21 April 2006 we captured another *L. r. ruhstrati* (587 mm SVL, 178 mm TL, 22.3 g prior to dissection) in the same area and maintained it in captivity until its death on 30 May 2006. Both specimens were dissected and inspected for parasites. Parasites were found in the vicinity of the trachea, lungs, liver, and fat reserves. All of the parasites were identified as *R. orientalis* and deposited in the United States Parasite Collection, Beltsville, Maryland (USNPC 100468). To our knowledge this is the first report of *R. orientalis* parasitizing *L. r. ruhstrati*.

MICRURUS ANCORALIS (Regal Coralsnake). **DIET**. Snakes of several phylogenetic groups and some raptorial birds are known to prey on caecilians (Taylor 1968. The Caecilians of the World. A Taxonomic Review. University of Kansas Press, Lawrence. 848 pp.). Specimens of *Micrurus corallinus* and *M. ancoralis* with caecilians in their stomachs have been reported (Boulenger 1913. Proc. Zool. Soc. London 1913:1019–1038). There are also reports of caecilian consumption by colubrids and other fossorial elapids (Gower et al. 2004. Afr. J. Ecol. 42:83–87). According to Roze (1996. Coral Snakes of the Americas: Biology, Identification, and Venoms. Krieger Publishing Co., Malabar, Florida. 328 pp.), at least nine species of coralsnake prey upon caecilians, and some appear to be caecilian specialists (e.g., *M. mipartitus* and *M. bocourti*). Here we present two additional observations of coralsnakes (*Micrurus*, Elapidae) feeding on caecilians.

On 2 May 2002 at 1530 h one of us (JFF) along with J. A.

Chaves observed a *Micrurus ancoralis ancoralis* (ca. 1300 mm TL) struggling with a *Caecilia* cf. *nigricans* at Bilsa Biological Station (0.46°N, 79.8°W, 400 m elev.), Esmeraldas Province, Ecuador. The *M. ancoralis* was biting the caecilian by the latter's lower jaw, while the caecilian had a hold of the snake's upper jaw. The pair struggled for over an hour. When we left the site both animals were still entangled. The tail of the caecilian was in a burrow but we estimate the caeclian's total length to be longer than the coral snake (ca. 1500 mm TL).

Campbell and Lamar (2004. The Venomous Reptiles of the Western Hemisphere. Volume I. Comstock Publishing Associates, Ithaca, New York. 898 pp.) suggest that *M. ancoralis* feeds on small snakes. Our observations and those of Boulenger (*op. cit.*) suggest that caecilians may comprise an important component of *M. ancoralis* diet. Direct observation of coralsnake predation upon caecilians is rare (Burger 1997. Bull. Chicago Herpetol. Soc. 32:145., Kupfer et al. 2003. Amphibia-Reptilia 24:212–215.). Our observation of headfirst ingestion is consistent with the inference that this is the most common pattern (Gower et al., *op. cit.*). Nevertheless, we believe this is the first observation of a caecilian struggling with a coralsnake after it appeared to have been envenomated.

We thank D. Salazar V., J. M. Guayasamin, J. Karubian, T. Smith, L. A. Coloma, and M. Bustamante for assistance. The Center for Tropical Research, University of California at Los Angeles, provided funding.

NERODIA ERYTHROGASTER (Yellow-bellied Watersnake). **DIET.** The diet of *Nerodia erythrogaster* consists almost entirely of fish and amphibians, with this species consuming more amphibians than other watersnake species (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. University of Oklahoma Press, Norman. 438 pp.). Moreover, a Louisiana population exhibited an ontogenetic shift in which snakes under 500 mm SVL largely consumed fish whereas individuals over 500 mm SVL largely consumed anurans (Mushinsky et al. 1982. Ecology 63:1624–1629). Here, we report a new anuran prey species for *N. erythrogaster* that was consumed by a snake under 500 mm SVL.

On 18 July 2006 at ca. 0020 h we collected a male *N. erythrogaster* (342 mm SVL, 536 mm total length, 23.4 g after prey removal) in a flooded, temporary wetland on the north side of Farm-to-Market Road 253, 2.0 road miles W of Texas Highway 87, Newton Co., Texas (30.4275°N, 93.8369°W). Numerous *Hyla squirella* were calling in the wetland. The abdominal region of the snake was noticeably distended, and later examination of the stomach contents revealed five adult male *H. squirella* with some decomposition to the head and forelimbs of the most posteriorly positioned treefrog. The combined mass of the five *H. squirella* was 10.5 g yielding a combined relative prey mass of 0.45. Although *H. chrysoscelis* and *H. cinerea* have been reported as prey items of *N. erythrogaster,* to the best of our knowledge this is the first time *H. squirella* has been reported as a prey item. All specimens were deposited in the Texas Natural History Collection (TNHC 65206).

NOTECHIS SCUTATUS (Australian Tiger Snake**). INJURIES.** Carnac Island in Western Australia hosts a large population of *Notechis scutatus* (Bonnet et al. 1999. Behav. Ecol. Sociobiol. 46:267–272). Adult *N. scutatus* in this population feed primarily on *Larus novaehollandiae* (Silver Gull) chicks. Adult *L. novaehollandiae* defend their progeny by pecking at the snake's head. Consequently, many snakes sustain head injuries, and of the estimated 400 adult snakes that appear to thrive on Carnac Island, 7.5% are totally blind and 6.6% half blinded. However, sight does not appear to be critical to the capture of their primary prey, abundant and sessile *L. novaehollandiae* chicks (Aubret et al. 2006. Austr. J. Zool. 303:894–903). This may explain why these injured snakes survive, eat and reproduce just as well as their intact counterparts (Bonnet et al., *op. cit*.). Here we present evidence of comparable injuries in two other island populations of *N. scutatus*.

In July 2007, an adult female *N. scutatus* with a large (ca. 2.5 x 2.5 cm), healed scar on the left side of her head was captured on Hopkins Island, South Australia (34.964°S, 136.060°E). A large area of tissue and bone as well as the left eye were missing. The left fang was embedded in scar tissue and non-functional. The snake had a low body mass for its length (1130 mm SVL, 356 g), however this was the case for most of the snakes on the island (pers. obs.). The injury appeared to be quite old, indicating that this snake has continued to survive despite its severe head injuries. A large adult male *N. scutatus* with a large, healed scar at mid-body was also captured on Hopkins Island. We presume that such injuries are due to attacks by large predatory birds. No other terrestrial snake predators occur on Hopkins Island. *Haliaeetus leucogaster* (White-breasted Sea Eagle) and *Aquila audax* (Wedge-tailed Eagle) are both present on Hopkins Island and both appear capable of attacking adult *N. scutatus* and inflicting severe injuries.

Furthermore, on a recent (January 2008) trip to Christmas Island (39.687°S, 143.831°E) off the coast of King Island, Tasmania, we captured and measured 33 adult *N. scutatus* (17 males, 16 females) and found that three large adult males presented injuries to their heads. Such injuries were characteristic and recognized (from numerous observations on Carnac Island tiger snakes) as being attacks from nesting birds defending their chicks. Many bird species nest on Hopkins islands, including *Puffinus tenuirostris* (Short-Tailed Shearwater), *Eudyptula minor* (Little Penguin), and *L. novaehollandiae*. Chicks of all three of these species are preyed upon by *N. scutatus*. However there is no evidence that shearwaters or penguins defend their hatchlings from the snakes, whereas *L. novaehollandiae* have been observed defending their hatchlings (Bonnet et al., *op. cit.*).

These observations further demonstrate the surprising ability of wild snakes to withstand large injuries and survive despite the loss of sensory (eye) or predatory (fang) equipment.

OXYBELIS AENEUS (Narrow-Headed Brown Vine Snake). **BEHAVIOR.** *Oxybelis aeneus* diet consists of lizards, frogs, birds, and mammals (Savage 2002. The Amphibians and Reptiles of Costa Rica. University of Chicago Press, Chicago, Illinois. 934 pp.). Here we report a possible predation event by *O. aeneus* upon the non-native gecko, *Hemidactylus frenatus* (House Gecko).

On 20 July 2007, we found an *O. aeneus* perched on a wall with a *H. frenatus* in its mouth on the Gandoca-Manzanillo Wildlife Refuge, Limón Province, Costa Rica (9.637889°N, 82.705222°W, WGS84; 3 m elev.). The snake was in a vertical, head down position and had seized the gecko's left hindlimb; the gecko was simultaneously biting the snake on the head (Fig. 1). The snake moved up and out of sight while the two were interlocked. Although not confirmed, we assume that the snake consumed the gecko. *Hemidactylus frenatus* has recently invaded Costa Rica and is commonly encountered in buildings, it is an abundant accessible prey for a variety of predators. However, only *Troglodytes aedon* (House Wren) has been reported preying on *H. frenatus* in Costa Rica (Barquero and Hilje 2005. Wilson Bull. 117:204–205). Our observation is noteworthy because it is the first report of apparent predation by a native reptile on non-native *H. frenatus* in Costa Rica.

FIG. 1. *Oxybelis aeneus* attempting to consume *Hemidactylus frenatus* at Gandoca-Manzanillo Wildlife Refuge, Limón Province, Costa Rica.

PORTHIDIUM HESPERE (Western Hognose Pitviper). **DIET**. *Porthidium hespere* is a rare pitviper known only from two specimens collected in the coastal plain of Colima and Michoacan, México (Campbell and Lamar 2004. Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York. 898 pp.). Very little is known about its ecology or natural history. On the night of 11 August 2005, a specimen (MZFC 19742) was found DOR in the vicinity of El Faro de Bucerias, Municipality of Aquila, Michoacan, Mexico (Goldberg et al. 2008. Herpetol. Rev. 39:99). Posterior examination of stomach contents revealed the remains (hind legs and vertebrae) of an *Ameiva undulata* (Rainbow Ameiva). Other members of the genus *Porthidium* prey on *Ameiva* and other lizards (Campbell and Lamar 2004, *op. cit.*). This is the first reported prey of *P. hespere* and only the third known specimen with precise locality data.

I thank C. Grünwald, E. Dugan, and J. Collins for assistance.

PSEUDONAJA TEXTILIS (New Guinea Brownsnake). **ATTEMPTED OPHIOPHAGY.** *Pseudonaja textilis* is a widely distributed and commonly encountered medically important elapid in eastern Australia. It was first collected in Papua New Guinea (PNG) in 1953, by the 4th Archbold Expedition to northern Milne Bay Province, (McDowell 1967. J. Zool. 151:497–543), and assumed to represent a WWII or post-war introduced population (Slater 1968. A Guide to the Dangerous Snakes of Papua. 2nd ed. V. P. Bloink, Port Moresby. 22 pp.). Additional records exist for Milne Bay, Oro and Central Provinces (O'Shea 1996. A Guide to the Snakes of Papua New Guinea. Independent Group, Port Moresby. 239 pp.; Williams et al. 2008 Zootaxa 1703:47–61), but it is uncommon in PNG. It has been reported as common in southeastern West Papua (Indonesia) (Kuch and Yuwono. 2002 Herpetozoa 15:75–78.). Recent work on the zoogeographical history and distribution of *P. textilis* in New Guinea suggests a natural origin rather than an introduction (Williams et al., *op. cit.*).

This note constitutes the first field-based feeding record for *P. textilis* from PNG and also represents deviation from the typical prey preferences of adult *P. textilis*. Australian *P. textilis* exhibit catholic diets, summarized as 9% frogs, 49% reptiles (3.7% snakes), 1% reptile eggs, 2% birds, and 39% mammals (Shine 1991. Australian Snakes: A Natural History. Reed, Sydney. 223 pp.), although an ontogenetic shift in diet preferences exists (Shine 1989. Herpetologica 45[2]:195–207). Snakes up to 600 mm SVL prey on ectotherms, while endotherms are the preferred prey of adult snakes. Most reptiles in the diet are lizards, with occasional reports of elapids being taken: *Denisonia devisi* (x1), and *P. textilis* (x2), and unidentified elapids (x3) in New South Wales (Shine 1989, *op. cit.*) and *P. textilis* (x1) in captivity (Neindorf, pers. comm.).

Between 21–23 October 2003, MOS visited Heropa oil-palm mini-estate, near the Popondetta to Buna road (8.75°S, 148.39°E) and part of Higaturu Plantations, Oro Province, PNG, to collect live *P. textilis* for a snakebite and venom research project, under the auspices of the Australian Venom Research Unit (AVRU), University of Melbourne. Six *Pseudonaja* were sighted and three

FIG. 1. *Candoia paulsoni mcdowelli* (top), succumbed to envenomation during a predation attempt by a *Pseudonaja textilis*. The *Candoia* had previously consumed a *Sphenomorphus jobiensis* (bottom). Photograph by Mark O'Shea.

captured, the first Oro Province specimens collected since the mid-1960s.

One specimen, a female (981 mm SVL, 1210 mm TTL), was sighted at 1100 h, following a period of light rain, lying alongside and parallel with a low 'frond-row' of dead palm fronds, between oil-palms. It was in the process of swallowing a *Candoia paulsoni mcdowelli* (McDowell's Bevel-nosed Ground Boa) that had been envenomed but was still alive. Although Australian *P. textilis* are reported to use constriction to subdue prey, the *Pseudonaja* was lying almost full length and was not constricting or restraining the *Candoia*, two thirds of which protruded from its mouth. Disturbed, the *Pseudonaja* regurgitated the *Candoia* and attempted to flee, but was caught. The *Candoia*, a female (445 mm SVL, 525 mm TTL) was also collected, but rapidly succumbed to the venom. It contained a *Sphenomorphus jobiensis* (Jobi Skink; 85 mm SVL, 180 mm TTL) (Fig. 1).

Snakes are representative of the limbless, elongate 'Type IIb' prey taken by many elapids (Cundall and Greene 1999. *In* Schwenk [ed.], Feeding: Form, Function, and Evolution in Tetrapod Vertebrates, pp. 293–333. Academic Press, San Diego, California) but adult Australian *P. textilis* are not noted to be especially ophiophagous, showing a preference for 'Type III' prey such as small mammals. All three New Guinea *P. textilis* collected by MOS fed readily on rat pups within 10 days of captivity. This record of ophiophagy is the first wild feeding record for PNG *Pseudonaja* and the first record of a *Pseudonaja* preying on a boid, although the endemic New Guinea elapid *Micropechis ikaheka* has previously been reported to prey on *Candoia aspera* (O'Shea 1994. Herpetol. Rev. 25:70).

We thank Wolfgang Wüster, Graham King, John Hula, Gabby Chris, Rick Shine, and Rex Neindorf.

Submitted by **MARK O'SHEA** (e-mail: osheam@unimelb.edu.au) and **DAVID WILLIAMS** (e-mail: d.williams4@pgrad.unimelb.edu.au), Australian Venom Research Unit, Department of Pharmacology, University of Melbourne, Parkville, Victoria, 3010, Australia.

PSEUSTES POECILONOTUS (Bird-eating Treesnake). **PREDATORS.** The diet of *Pseustes poecilonotus* is known to include birds and bird eggs (Campbell 1998. Amphibians and Reptiles of Northern Guatamala, the Yucatan, and Belize. University of Oklahoma Press, Norman. 380 pp.). However, other than antbirds (Thamnophilidae), interactions with specific avian prey species appear to be lacking in the literature (Oniki 1979. Biotropica. 11:60–69; Weatherhead and Blouin-Demers 2004. J. Avian Biol. 35:185–190; Willis 1972. Ornithol. Monogr. 10:1–162).

On 11 August 1996 at approximately 1400 h I watched two adult *Ramphastos swainsonii* (Chesnut-mandibled Toucans) dive repeatedly at a nest hole cavity located ca. 15 m high in the trunk of a dead tree near the 300 meter mark of the Sendero Oriental Trail at La Selva Biological Station, Costa Rica (10.43°N, 83.98°W). Observation with binoculars revealed that a *P. poecilonotus* (ca. 1.4 m total length) was clinging to the tree trunk just outside the nest hole opening. The two *R. swainsonii* continued to dive at and harass the snake for several minutes before the snake fell from the tree and landed on a log a few meters from where we were standing. I could not tell whether the snake had lost its grip or whether it had been knocked off the tree by the *R. swainsonii*. The snake's head had blood on it, but it wasn't clear if its injuries were sustained from the fall, or from the toucans. The *P. poecilonotus* was momentarily stunned, and I grabbed it by the tail, whereupon it spread its neck and began striking at me. I released the *P. poecilonotus* at the capture site.

I could find no records in the literature of *P. poecilonotus* attempting to prey on *R. swainsonii* or any other toucan species. Further, foraging observations documented in the literature seem to indicate that *P. poecilonotus* is most often seen foraging in lower level vegetation (Willis, *op. cit.*), so seeing one attempting to predate a nest high in the canopy may represent an unusual event (D. Graham, pers. comm.). Alternatively, it may be that human observations of *P. poecilonotus* tend to be limited to lower vegetation, missing possible foraging by the snake at higher levels of the canopy.

I thank D. Graham for assistance.

RHINOCHEILUS LECONTEI TESSELATUS (Texas Longnosed Snake). **LONGEVITY.** On 25 June 1980, I collected a male *Rhinocheilus lecontei tesselatus* (ca. 260 mm SVL) at a public camping ground adjacent to the Pecos River (Jim White Campground, now Lake Carlsbad Recreation Area), Carlsbad, Eddy County, New Mexico. I maintained this animal in captivity until its death on 12 August 2007. From the time of its capture until August 1989, the snake was fed a diet of *Sceloporus occidentalis* (Western Fence Lizard), *Uta stansburiana* (Side-blotched Lizard), and *Eumeces skiltonianus* (Western Skink). Refused prey items included *S. occidentalis* eggs and subadult *Elgaria multicarinata* (Southern Alligator Lizard). From August 1989 until its death, the snake was fed weanling *Mus musculus* and neonate *Rattus nor-*

vegicus. At time of death, the snake measured 645 mm SVL and 105 mm tail length. The size at time of collection, indicates that it likely hatched in 1978 or earlier, making this snake at least 29 years old when it died. Previous records for this species (Slavens 1981. Inventory of Live Reptiles and Amphibians in North American Collections, Current January 1, 1981. Woodland Park Zoological Gardens, Seattle, Washington; Snider and Bowler 1992. Longevity of Reptiles and Amphibians in North American Collections, 2nd ed. Herpetol. Circ. 21) do not indicate a specimen older than 22 years. The specimen is deposited in the Texas Natural History Collections (TNHC 66571).

Submitted by **STEPHEN J. MULLIN**, Department of Biological Sciences, Eastern Illinois University, Charleston, Illinois 61920, USA; e-mail: sjmullin@eiu.eiu.

SIBON LONGIFRENIS (Drab Snail-eater). **REPRODUCTION.** The genus *Sibon* is one of four groups of neotropical snake specialized for foraging on snails, slugs, and also amphibian eggs (Montgomery et al. 2007. Herpetol. Rev. 38:343). *Sibon longifrenis* is a small nocturnal and arboreal species previously found in Honduras, Costa Rica, and Panama. In Costa Rica it inhabits undisturbed Atlantic Lowland Wet and Moist Forests, Premontane Wet Forests, and Rainforest. It is a seldom seen snake that inhabits deep shady forest (Leenders 2001. A Guide to the Reptiles and Amphibians of Costa Rica. Zona Tropical, Miami, Florida. 305 pp.; Savage 2002. Amphibians and Reptiles of Costa Rica. University Chicago Press, Chicago, Illinois. 934 pp.).

On 14 November 2002, while conducting transect-based surveys, I found a female *S. longifrenis* (288 mm SVL, 135 mm tail, 9.7 g) in the forests of Caño Palma Biological Station, Tortuguero, Limón Province. The snake was moving across a palm tree leaf (*Manicaria saccifera*) at a height of ca. 2 m in an area of wet primary swamp forest (25.4°C, 97%RH). I captured the snake and held it overnight in order to verify identification and measure it. During the night the snake laid two elongate, white eggs (10.0 x 26.1 mm, 1.24 g; 10.1 x 24.8 mm, 1.25 g) in a terrarium. After laying her eggs, the snake weighed 7.1 g. The eggs were placed inside a small terrarium in conditions intended to mimic natural circumstances. Unfortunately by 25 December 2002 both eggs had brown fungi on their surfaces and inspection revealed partially developed dead embryos inside.

Guyer and Donnelly (2005. Amphibians and Reptiles of La Selva, Costa Rica and the Caribbean Slope. University of California Press, Berkeley. 367 pp.) reported *S. longifrenis* as 'presumably an egg-layer.' To the best of my knowledge, this is the first report of clutch size in *S. longifrenis*. Egg-laying has been reported for only a handful of *Sibon* species, but all previously reported clutch sizes range from 2–9 eggs (Kofron 1987. J. Herpetol. 21:210–225; McCoy 1990. Carib. J. Sci. 26:162–166; Campbell 1998. Amphibians and Reptiles of Northern Guatemala, the Yucatan, and Belize. University of Oklahoma Press, Norman, Oklahoma. 380 pp.). November and December are wetter periods for the Tortuguero region and Caño Palma Biological Station receives most of its rainfall around this time.

I thank the Canadian Organization for Tropical Education and Rainforest Conservation, Ministerio de Recursos Naturales Energia y Minas, and Farnborough College of Science and Technology for permissions and assistance.

THAMNOPHIS ATRATUS ATRATUS (Santa Cruz Gartersnake). **DIET**. The interaction between the newt *Taricha granulosa* and the gartersnake *Thamnophis sirtalis* provides a model system for the study of predator-prey coevolution (e.g., Brodie and Brodie 1999. Bioscience 49:557–568). Newts of the genus *Taricha* possess tetrodotoxin (TTX) in their skin and other tissues (Mosher et al. 1964. Science 144:1100–1110; Wakely et al. 1966. Toxicon 3:195–203), which acts as a powerful chemical defense against nearly all potential predators (Brodie 1968. Copeia 1968:307–313). Despite the fact that TTX is a potent neurotoxin, *T. sirtalis* in a number of California and Oregon populations prey on *T. granulosa* (Brodie and Brodie 1990. Evolution 44:651–659; Brodie and Brodie 1991. Evolution 45:221–224). In fact, concentrations of TTX in *T. granulosa* and levels of resistance in *T. sirtalis* generally covary over much of the West Coast in a pattern consistent with an evolutionary arms-race of adaptation and counter-adaptation (Brodie et al. 2002. Evolution 56:2067–2082; Hanifin et al. 2008. PLoS Biol. 6:e60). Until recently, this TTX-mediated coevolution was thought to include only two ecological partners, *T. sirtalis* and *T. granulosa*. However, a similar interaction between gartersnakes and newts was recently discovered in the Sierra Nevada Mountains of California; *T. couchii* prey on both *T. torosa* (Brodie et al. 2005. J. Chem. Ecol. 31:343–356) and *T. sierrae* (Wiseman and Pool 2007. Herpetol. Rev. 38:344–345) and are resistant to TTX at levels concordant with toxicity in sympatric *T. torosa* (Brodie et al. 2005, *op. cit.*). Here we detail a field observation of a *T. atratus* preying on a *T. granulosa*. Our report is significant because it is the first to document predation by *T. atratus* on metamorphosed *Taricha* in the wild, and hints at yet a third arms-race between gartersnakes and newts.

On 13 October 2006 at 1411 h, at Monte Bello Pond (MB05) in the Santa Cruz Mountains, Santa Clara County, California (37.32108°N, 122.18548°W; 576 m elev.), RRG observed an adult *T. atratus atratus* (~ 75 cm SVL) swim ashore with a subadult *T. granulosa* (~ 5 cm SVL) firmly held in its mouth (Fig. 1). The snake settled on the south edge of the pond, characterized by a gentle grade and only sparse vegetation, where it held the newt high off the substrate (~ 15 cm) but kept the majority of its own body anchored in the shallows. The snake gripped the newt through the midsection and proceeded to manipulate the prey deeper into its mouth. The newt struggled to free itself and appeared to exude a milky white liquid along its dorsal surface (glandular secretions including TTX; Cardall et al. 2004. Toxicon 44:933–938), but by 1414 h (3 min) the snake had already succeeded in swallowing the newt tail-first. The snake briefly rested (1 min) before turning back into the pond and slowly swimming away, apparently unaffected by its prey.

Taricha larvae have been reported in the diet of *T. atratus* (Fitch 1940. Univ. California Publ. Zool. 44:1–150; Fitch 1941. California Fish Game 27:2–32; Fox 1951. Univ. California Publ. Zool. 50:485–530; Kuchta 2005. *In* Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Populations

FIG. 1. An adult Santa Cruz Gartersnake (*Thamnophis atratus atratus*) consuming a subadult Rough-skinned Newt (*Taricha granulosa*) in Monte Bello Pond, Santa Clara County, California (MVZ 257750).

Vol. 2, pp. 904–908. Univ. California Press, Berkeley, California). However, newts possess little if any TTX before metamorphosis (Twitty and Johnson 1934. Science 80:78–79), so predation of newt larvae may occur commonly by sympatric gartersnakes and probably does not indicate physiological resistance to TTX. The only account that mentions consumption of transformed *Taricha* by *T. atratus* suggests this occurred in captivity and provides no information on the source of the specimens (Fox 1951, *op. cit.*). Even naïve gartersnakes that do not co-occur with some toxic amphibians will attempt to eat such deadly prey in the laboratory (e.g., Brodie at al. 1991. Biotropica 23:58–62), so captive observations are not especially revealing. Furthermore, because of extensive geographic variation in newt potency (Hanifin et al. 2008, *op. cit.*), locality information is critical in understanding the complex pattern of match and mismatch (hotspots and coldspots) between newt toxicity and TTX resistance across the landscape (Brodie et al. 2002, *op. cit.*). Our account of a natural predation event by *T. atratus* on a transformed *T. granulosa* suggests another parallel arms-race between gartersnakes and newts and could lead to a number of exciting evolutionary and ecological investigations. We hope other naturalists will continue to add pieces to this fascinating and unfolding coevolutionary puzzle (e.g., Fellers et al. 2007. Herpetol. Rev. 38:317–318).

We thank E. D. Brodie, Jr for verifying newt species, and C. L. Spencer for accessioning photo vouchers (MVZ 257749–257754).

TROPIDOPHIS PAUCISQUAMIS (Brazilian Dwarf Boa)**. DIET AND CAUDAL LURING**. *Tropidophis paucisquamis* is a semi-arboreal snake typically found in bromeliads in the Atlantic forests of Brazil (Carvalho 1951. Rev. Bras. Biol. 11:239–248). However, basic aspects of its biology remain unknown, since it is rarely observed and specimens are rare in collections (Amaral 1930. Bol. Mus. Nac. 4; Hedges 2002. Bull. Nat. Hist. Mus. Lond. [Zool.] 68:83–90). Feeding and behavioral information are restricted to captive specimens or are speculative (Amaral 1978. Serpentes do Brasil: Iconografia Colorida. Brazilian Snakes: a Color Iconography. Melhoramentos/EDUSP, São Paulo, Brazil; Carvalho, *op. cit.*). Here, we present the first report of feeding and tail displays by two wild *T. paucisquamis* recorded on the same night and location.

On 17 December 2004 at 2030 h at Pilar do Sul Municipality, São Paulo State, Brazil (23.93ºS, 47.67ºW, 780 m elev.) we watched as an adult *T. paucisquamis* (315 mm SVL, 42 mm tail length) left the shelter of a leaf (*Bathyza* sp., ca. 1.5 m above ground) and defecated. The snake stayed perched and immobile we collected it at 0230 h on 18 December 2004. Upon collection, the snake regurgitated a *Hypsiboas caipora* (33 mm SVL, 2.5 g) which it had swallowed headfirst. It was raining and the air temperature was 18–19°C. The following day the snake was found coiled in a ball. The snake was photographed and released and the treefrog (CFBH 9336) was deposited in Célio Fernando Baptista Haddad collection, Laboratório de Herpetologia, Instituto de Biociências, Universidade Estadual Paulista, Rio Claro, São Paulo State, Brazil.

A second snake was foraging a few m away and we observed it from 2000 h on 17 December 2004 until 0230 h on 18 December 2004. This snake stopped on two occasions and lured with its tail. On the first occasion, the snake was stretched out on a leaf of *Calathea communis* (Marantaceae), except for the tail, which was elevated and undulated in a sinusoidal manner for ca. one minute. On the second occasion, the body was again stretched out. However, in this case the sinusoidal undulations of the tail were made while the tail was in contact with the plant stem, and the tail was dragged along the stem for ca. 30 seconds. In both cases tail movements were made from a stationary position and in the presence of two male *Hypsiboas caipora* (ca. 3 m from the snake). The contrasting color of the tail (with the body) and the observations of tail displays in the presence of prey by *T. paucisquamis* indicate that the species uses its tail as a lure, although additional observations are necessary to confirm this hypothesis.

Submitted by **ANDRÉ PINASSI ANTUNES** (e-mail: aapardalis@gmail.com) and **CÉLIO FERNANDO BAPTISTA HADDAD**, Laboratório de Herpetologia, Departamento de Zoologia, Instituto de Biociências, Universidade Estadual Paulista, 1515, Rio Claro, 13506-900, São Paulo, Brazil.

TYPHLOPS BRONGERSMIANUS (Blindsnake). **OWL PREDATION**. *Typhlops brongersmianus* is relatively small (ca. 300 mm total length as adults) and occurs from Uruguay to Venezuela (Lema 1982. Iheringia 61:3–7.; Lema 1987. Acta Biologica Leopoldensia 9:225–240). The fossorial *T. brongersmianus* occurs in different enviroments, but primarily in sandy soils. In this habitat, it feeds on small terrestrial invertebrates (Freitas 2003. Serpentes Brasileiras. Bahia, Brazil. 119 pp.).

On 3 February 2007, I encountered a road-killed adult (sex not determined) Tropical Screech Owl (*Megascops choliba*) south of Rodovia do Sol at kilometer 32 on route ES 060. The area around

kilometer 32 is transitional between salt marsh and mangroves (Venturini et al. 1996. Aves e Mamíferos na Restinga Parque Estadual Paulo César Vinha Setiba. Guarapari, Espírito Santo. Secretaria de Estado do Desenvolvimento Sustentável. Governo do Estado do Espírito Santo, Vitória). During examination of the stomach contents of the owl on 7 November 2007, I found an adult male *T. brongersmianus* severed into two pieces. The anterior piece was 6.8 mm long, whereas the posterior one was 8.3 mm. Besides the *T. brongersmianus*, the stomach also contained two leptodactylid frogs (not further identifiable because of the degree of digestion), 14 ants, and two orthopterans.

Megascops choliba, a small (97–134 g) crepuscular owl, inhabits open habitats such as forest edges, Cerrado, rural fields, and sometimes urban localities. It feeds on insects, especially orthopterans and beetles, and may also capture small rodents, snakes, lizards, and anurans (Motta-Junior 2002. J. Raptor Res. 36:332–334; Sick 1997. Ornitologia Brasileira. Ed. Nova Fronteira, Rio de Janeiro, Brazil. 862 pp.). Among the seven stomachs of *M. choliba* analyzed, only one had vertebrate prey. This is the first record of *T. brongersmianus* in the diet of *M. choliba*.

The *T. brongersmianus* specimen (MBML 2203) was deposited in the Herpetological Collection of the Museu de Biologia Prof. "Mello Leitão." I thank Concessionária Rodosol S.A. for permits, Flávia Araújo for help in analysis, Thiago Maciel de Castro for species identification, Gustavo Machado Prado for valuable suggestions on the manuscript, and Luisa Maria Sarmento Soares for English translation.

Submitted by **MIKAEL MANSUR MARTINELLI**, Setor de Zoologia, Museu de Biologia Prof. "Mello Leitão," Avenida José Ruschi, 4, CEP 29650-000, Santa Teresa, Espírito Santo, Brazil; e-mail: mansurmartinelli@yahoo.com.br.

VIRGINIA PULCHRA (Mountain Earth Snake). **LONGEVITY, REPRODUCTION, AND GROWTH.** Longevity and growth data are lacking for *Virginia pulchra* (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C.; Slavens and Slavens 1997. Reptiles and Amphibians in Captivity: Breeding, Longevity, and Inventory Current January 1, 1996. Slaveware, Seattle, Washington; Snider and Bowler 1992. Longevity of Reptiles and Amphibians in North American Collections. 2nd ed. SSAR Herpetol. Circ. No. 21). Herein I report, to my knowledge, the first longevity record for *V. pulchra* as well as observations on reproduction and growth.

On 4 June 2004 a gravid female *V. pulchra* (225 mm SVL; 265 mm total length; 10 g) was found under rocks, on a sparsely vegetated slope at State Game Land 86, Warren County, Pennsylvania, USA. The snake was maintained in captivity and produced a litter of five young on 9 August 2004. This date is earlier than the earliest parturition date of 18 August observed by Pisani (1971. J. Herpetol. 5:207–208). All neonates were female, 88–93 mm total length, and the litter totaled 2.75 g (34.4% of female's postpartum mass). Richmond (1954. Ann. Carnegie Mus. 33:251–260) also reported an all-female litter born to a captive female *Virginia* sp. Furthermore, Bothner and Moore (1964. Copeia 1964:709–710) noted two of nine litters that contained skewed sex ratios (7 F:1M; 5F:1M). On 14 July 2007, after 3 years, 1 month, and 10 days in captivity the specimen was found dead in her enclosure. During that time, she had increased in length by 13.3% (255 mm SVL, 300 mm total length) and weighed 11 g. Because this species matures during its second year (Ernst and Ernst 2003, *op. cit.*), it is reasonable to assume that this snake was at least five years old at the time of its death.

The specimen (TREC R-025) is deposited in the collection of the Tom Ridge Environmental Center, Erie, Pennsylvania. A shed skin (MHP 11835) obtained from the specimen is deposited in the Sternberg Museum of Natural History, Fort Hays University, Lawrence, Kansas.

I thank J. Beane, J. Collins, and M. Lethaby for assistance.

Submitted by **BRIAN S. GRAY**, 1217 Clifton Drive, Erie, Pennsylvania 16505, USA; e-mail: brachystoma@hotmail.com.

ZAOCYS DHUMNADES (Big-Eye Rat Snake). **DIET.** *Zaocys dhumnades* is a large diurnal snake from China and Taiwan that has been reported to eat amphibians, rodents, small fish, and lizards (Kuntz 1963. Snakes of Taiwan. Quart. J. Taiwan Mus. 16:15–17; Zhou and Jiang 2004. Cons. Biol. 18:1386–1394).

On 9 May 2007, a DOR male *Z. dhumnades* (1206 mm SVL, 599 mm tail length, 526 g) was found on the roadside, where it appeared to have been trapped on the road by a barrier in the Ilan section of the North Crossroad, Taiwan (24.6439ºN, 121.5119ºE, 600 m elev.). A partially digested female *Buergeria robustus* (Brown Treefrog) was protruding from the snake. According to previous dietary records, *Z. dhumnades* preys mainly on lentic anurans (e.g., *Bufo* or *Rana*; Pope 1935. Natural History of Central Asia. Volume X: The Reptiles of China. American Museum of Natural History, New York). *Buergeria robustus* typically inhabit trees and can be found up to 7 m above ground (Hou and Kuo 1996. Notes and Newsletter of Wildlifers 4:6–7). However, during the breeding season (late April–early June) they aggregate along mountain creek banks at elevations below 1000 m. *Trimeresurus stejnegeri* has been observed to use these localities as ambush sites (JJM, unpubl. obs.). Our observations suggest that seasonal breeding aggregations of some arboreal frogs on the ground provide an occasional food source for opportunistic ophidian predators. We believe this to be the first reported instance of *Z. dhumnades* predation on *B. robustus*.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother [ed.] 2008. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico*. SSAR Herpetol. Circ. 37:1–84, available from SSAR Publications Secretary, ssar@herplit.com; for Mexico as it appears in Liner and Casas-Andreu 2008, *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico*. Herpetol. Circ. 38:1–162), LOCALITY (use metric for distances and give precise locality data, including lat/long coordinates in **decimal degrees** and cite the map datum used), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author; curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief and must adhere to format used in this section; these should provide a geographic context for the new record), SUBMITTED BY (give name and address in full—spell out state or province names—no abbreviations). Please include distance from nearest previously known record (provide a citation or refer to existing vouchered material to substantiate your report). If publishing specific locality information for a rare or endangered species has the potential to jeopardize that population, please consult with the Section Editor at time of record submission. If field work and/or specimen collection occurred where permits were required, please include permit number(s) and authorizing agency in the text of the note.

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality photograph (print, slide, or digital file) may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Photographic vouchers *must* be deposited in a university or museum collection along with complete locality data, and the photographic catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary), subsequent issues of *Herpetological Review*, and other sources to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. **Do not submit range extensions unless a thorough literature review has been completed.**

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canada records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean Basin); **Indraneil Das** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments)**.** Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Schmitz, A., and T. Ziegler. 2003. Geographic distribution: *Sphenomorphus rufocaudatus*. Herpetol. Rev. 34:385.

CAUDATA – SALAMANDERS

AMBYSTOMA TIGRINUM (Eastern Tiger Salamander). USA: INDIANA: Pike Co.: Madison Township: ca. 0.4 km W of Bowman on Hwy 56 (38.48867ºN, 87.35124ºW, NAD 83). 31 March 2008. Nathan Engbrecht. Verified by Chris Phillips. Photo voucher in Illinois Natural History Survey (INHS 2008.d). Adult female found on road at night. New county record (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Acad. Sci. 404 pp.)

Submitted by **NATHAN ENGBRECHT (**e-mail: nengbrecht@dnr.in.gov), **ANGIE GARCIA, BETHANY GEBOY,** and **ZACK WALKER**, Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 E. Miller Drive, Bloomington, Indiana 47401, USA.

EURYCEA BISLINEATA (Northern Two-lined Salamander). USA: MICHIGAN: Tuscola Co.: Murphy Lake State Game Area (43.2813291°N, 83.45363036°W). 12 April 2008. Nicole Soderberg, Ernest Szuch, and Teresa Yoder. Verified by James Harding. University of Michigan Museum of Zoology (UMMZ i7, photo voucher). Individual was gravid; therefore, she was photographed and released at site of capture. Three additional specimens were recorded from Tuscola County; UMMZ i10, i11, i12, i13 photo vouchers; UMMZ i1, i2; photo vouchers and UMMZ 239001. First state record (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 587 pp.).

Submitted by **NICOLE SODERBERG**, **TERESA YODER,** and **ERNEST SZUCH**, Department of Biology, University of Michigan-Flint, Flint, Michigan 48502-1950, USA.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). USA: MARYLAND: Somerset Co.: 5.0 km W of Princess Anne off Pine Pole Rd. (38.21102°N, 75.74951°W; WGS 84). 18 April 2008. Nathan H. Nazdrowicz. Verified by Traci Hartsell. USNM 565980. One female found under sphagnum moss around a clutch of 28 eggs, and one unattended clutch of eggs observed in a semi-open canopy, grassy wetland. New county record (White and White 2007. Amphibians and Reptiles of Delmarva. Revised ed. Tidewater Publishers, Centreville, Maryland. 243 pp.).

HYLA GRATIOSA (Barking Treefrog). USA: TENNESSEE: Gibson Co.: Milan Army Ammunition Plant (35.8675°N, 88.7331°W). 08 October 2008. Eric Johansen, Nathan Parker, Seth McCormick, and Nathalie Smith. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 18943 [juvenile] and APSU 18944 [metamorph]). Collected in fishless pond at 1100 h. New county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Hard copy and Internet [http://www.apsu.edu/amatlas/] versions, the latter accessed 02 June 2008).

Submitted by **ERIC PAUL JOHANSEN** (e-mail: ejohansen14@apsu.edu), **NATHALIE SMTIH**, and **SETH McCORMICK**, Department of Biology and Center of Excellence for Field Biology, Austin Peay State University, Clarksville, Tennessee 37044, USA.

HYLA WRIGHTORUM (Arizona Treefrog). MEXICO: SONORA: Los Fresnos Ciénega, ca. 44 km NW Cananea (31.30845^{0}N, 110.42915^{0}W)**,** 1534 m elev. 25 August 1990. Peter L. Warren. Verified by T. C. Brennan. Arizona State University voucher photograph (ASU HP.59). Northernmost record for this species in Sonora and a 235 km NNW range extension from the closest record at El Chorro, 8 km NE of Nacori Chico, Sonora (UAZ 45595), although the closest out-of-country record is ca. 13 km N in Arizona (Gergus et al. 2004. Copeia 2004:758–769). A locality dot pictured on a map in Duellman (2001. Hylid Frogs of Middle America, Vol. 2. SSAR Contrib. to Herpetol. 18:i–x, 695–1159), which appears close to Los Fresnos Ciénega, was an apparent misplacement for a record from Yécora, Sonora (W. E. Duellman, pers. comm.). Additional individuals were observed by us during August and October 2006 in surrounding wetlands situated within the grassland ecosystem characteristic of the Los Fresnos Ciénega region. Typical habitat for this species was reported to be in meadows or slow-moving streams within pine-oak and pine-fir forest (Gergus et al. 2005. *In* M. J. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 461–463. University of California Press, Berkeley).

Submitted by **MICHAEL S. PRICE**, San Angelo Nature Center, 7409 Knickerbocker Road, San Angelo, Texas 76904, USA; e-mail: michael.price@sanangelotexas.us.

TRACHEMYS EMOLLI (Moll's Slider). EL SALVADOR: LA UNIÓN: Golfo de Fonseca: Municipio de Meanguera del Golfo: east-central shore of Pirigallo Island (13.1020°N, 87.4103°W; datum WGS 84), 0 m elev. 29 August 2007. Enrique Barraza and Ricardo Ibarra Portillo. Verified by John L. Carr. Museo de Historia Natural de El Salvador, San Salvador collection (MUHNES C-301654). Municipio de Intipucá: Playa El Icacal (13.1675°N, 88.005256 W; WGS84), 0 m elev. 11 May 2008. Carlos Funes. Verified by John L. Carr. The University of Kansas Natural History Museum Digital Archive (KUDA 002402–002405). New records for El Salvador (Köhler et al. 2006. The Amphibians and Reptiles of El Salvador. Krieger Publ. Co., Malabar, Florida. ix + 238 pp.), extending the species' range ca. 140 km NW of closest known localities in Lakes Managua and Nicaragua, in streams connecting the two lakes, and in Río San Juan near the Nicaragua-Costa Rica border (Legler 1990. *In* J. W. Gibbons [ed.], Life History and Ecology of the Slider Turtle, pp. 82–105. Smithson. Inst. Press, Washington, D.C.). The adult male from Pirigallo Island was found dead, lodged between rocks at 2 m depth in sea water. Because Pirigallo Island does not contain suitable freshwater habitat for *Trachemys*, it is likely that the specimen was blown out to sea from a nearby lagoon in the Gulf of Fonseca or from the Río Choluteca during a storm. The Playa El Icacal, male specimen was collected as it was swimming in an estuary near Río El Encantado. Legler (1990, *op. cit.*) noted the absence of *Pseudemys* (= *Trachemys*) records from suitable habitat in the lowland corridor from the Gulf of Fonseca to Lake Managua, but our records suggest that *T. emolli* occurs throughout this corridor in El Salvador, Honduras, and Nicaragua. However, we cannot eliminate the possibility that the species was introduced by the illegal wildlife trade that is rampant in the Gulf of Fonseca (O. Komar, pers. comm.).

Submitted by **RICARDO IBARRA PORTILLO**, Ministerio de Medio Ambiente y Recursos Naturales (MARN), Calle y Colonia Las Mercedes, km 5 y ½ carretera a Santa Tecla, San Salvador, El Salvador (e-mail: ribarra@marn.gob.sv); **VLADLEN HENRÍQUEZ,** Programa de Ciencias para la Conservación, SalvaNATURA, 33 Ave Sur #640, Colonia Flor Blanca, San Salvador, El Salvador (e-mail: vhenriquez@salvanatura.org); and **ELI GREENBAUM,** Department of Biological Sciences, University of Texas at El Paso, 500 West University Ave., El Paso, Texas 79968, USA (e-mail: egreenbaum2@utep.edu).

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). USA: FLORIDA: GILCHRIST CO.: Santa Fe River, 2.5 km upstream from Suwannee River (29.9030667ºN, 82.8672583ºW, datum WGS84). 27 February 2008. Travis M. Thomas. UF 153059. Verified by Kenneth L. Krysko. New county record and 37.6 km downstream from the closest known *T. s. elgans* (UF 153056–57) in Columbia County. Adult male (carapace length 150 mm, plastron length 140 mm) captured using baited hoop trap.

JOHNSTON**, Department of Natural Sciences, Santa Fe Community College, Gainesville, Florida 32606, USA (e-mail: jerry.johnston@sfcc.edu).

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). USA: FLORIDA: SUWANNEE CO.: Ichetucknee Springs State Park, Devil's Eye Spring, Ichetucknee River (29.9737194ºN, 82.7600556ºW; datum WGS84). 19 April 2008. Anthony Lau. Florida Museum of Natural History (UF 153060). Verified by Kenneth L. Krysko. New county record. Adult male (carapace length 140 mm, plastron length 127 mm) captured by hand while snorkeling. First known *T. s. elegans* collected in the Ichetucknee River, a tributary to the Santa Fe River, where multiple individuals of non-native *T. s. elegans* have been collected (Lau et al. 2008. Herpetol. Rev. 39:236–237).

Submitted by **ANTHONY LAU**, Department of Wildlife Ecology and Conservation, University of Florida, Gainesville, Florida 32611, USA (e-mail: alau0924@ufl.edu); and **GERALD R. JOHNSTON**, Department of Natural Sciences, Santa Fe Community College, Gainesville, Florida 32606, USA (e-mail: jerry.johnston@sfcc.edu).

SQUAMATA – LIZARDS

AMEIVA AMEIVA (Giant Ameiva). USA: FLORIDA: MONROE CO.: Grassy Key, jct Morton Street and Lemon Avenue (24.7629ºN, 80.9603ºW, WGS84). 21 September 2008. Renée Anderson. Two individuals observed foraging among leaves on ground. Florida Museum of Natural History photographic voucher (UF 153706). Verified by Kenneth L. Krysko. First record from the Florida Keys and a new county record. Extends range ca. 106 km SSW of the nearest known population at a reptile dealer's facility in Miami,

Miami-Dade Co. (UF 137671). Other *A. ameiva* were observed in the vicinity, suggesting an established population.

Submitted by **SCOTT HARDIN**, Florida Fish and Wildlife Conservation Commission, 620 South Meridian Street, Tallahassee, Florida 32399, USA (e-mail: scott.hardin@myfwc.com); **RENÉE ANDERSON**, Signs by Renée, 72 Coco Plum Drive, Marathon, Florida 33050, USA; and **KEVIN M. ENGE**, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA.

ANOLIS ALLISONI (Green Anole). HONDURAS: ATLÁNTIDA: Hotel Rotterdam, La Ceiba (15.4730°N, 86.4720°W; WGS84), near sea level. 13 May 2007. Alexander Gutsche and James R. McCranie. Verified by Steve Gotte. USNM 570550. First mainland record for this species in Honduras (McCranie et al. 2005. Amphibians & Reptiles of the Bay Islands and Cayos Cochinos, Honduras. Bibliomania!, Salt Lake City, Utah. xiii + 210 pp.). The specimen was captured at 1135 h on a small palm tree in the hotel garden. Observations of about ten additional specimens, including adult males and females and a subadult, indicate an established population that was likely introduced from nearby Islas de la Bahía, Honduras. Fieldwork of A. Gutsche was supported by German Research Fondation (DFG 444 HON 111/1/07).

Submitted by **JAMES R. McCRANIE,** 10770 SW 164th Street, Miami, Florida 33157-2933, USA (e-mail: jmccrani@bellsouth.net); and **ALEXANDER GUTSCHE**, Humboldt-Universität zu Berlin, Institut für Biologie, Abteilung Sinnesbiologie, Invalidenstr. 43, D-10115 Berlin, Germany (e-mail: alexander-gutsche@web.de).

ANOLIS EQUESTRIS (Knight Anole). USA: FLORIDA: Highlands Co.: 101 Green Dragon Drive, Lake Placid (27.295233°N, 81.370525°W, WGS84; elev. 36.5 m). 27 September 2005. Florida Museum of Natural History (UF 153968). New county record and extends the range ca. 78 km NE of the closest known locality at 5207 Palm Beach Boulevard, Fort Myers, Lee County (UF 145694). Polk Co.: 3832 Avenue Q NE, Winter Haven (28.03906°N, 81.72411°W, WGS84; elev. 44 m). 15 December 2007. UF 153967. New county record and extends the range ca. 86 km north of the closest known locality in Highlands County above (Camposano et al. 2008. Iguana 15[4]:24–31). Found dead in swimming pool. Specimens collected by Daniel Parker and verified by Kevin M. Enge.

Submitted by **DANIEL J. PARKER**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: sunshineserpents@earthlink.net); and **KENNETH L. KRYSKO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu).

COLEONYX VARIEGATUS (Western Banded Gecko). USA: NEVADA: Esmeralda Co.: Cuprite Hills, northwest of U.S. Highway 95 and State Route 266 intersection (37.52292°N, 117.20111°W, WGS84), 1500 m elev. 11 March 2008. Polly Conrad. University of Nevada at Reno (UNR 7725). A second specimen (UNR 7724) was found nearby in the Palmetto Mountains. Verified by Chris R. Feldman. Northernmost record for the species. These records extend the range of *C. variegatus* by 44.2 km NNE of UNR 7002 in Nye County, Nevada and 62.8 km ENE of MVZ 227787 in Inyo County, California. Two desiccated specimens were found inside hollow mine claim marker posts. There was no evidence of predation, thus the idea of birds dropping the lizards into the posts was ruled out. Along with several hundred individuals of many other lizard species, the geckos likely accessed the plastic hollow mine claim posts through perforations slightly above ground level, turning the posts into traps.

We thank Chris Feldman for assistance with museum records.

Submitted by **PAULETTE M. CONRAD,** Nevada Department of Wildlife, Diversity Division, 4747 Vegas Drive, Las Vegas, Nevada 89108, USA (e-mail: pconrad@ndow.org); and **PETER V. BRADLEY**, Nevada Department of Wildlife, Diversity Division, 60 Youth Center Drive, Elko, Nevada 89801, USA.

CTENOSAURA PECTINATA (Mexican Spiny-tailed Iguana). USA: FLORIDA: Broward Co.: Hollywood, N 56th Avenue (26.03661°N, 80.2005°W; WGS84; elev. <1 m). 22 October 2008. Raymond A. Mendez. Verified by Kevin M. Enge. Florida Museum of Natural History photographic voucher (UF 153801). New county record and extends known range of this species ca. 50 km N of closest known record near Old Cutler Road along Biscayne Bay, Miami-Dade County (Townsend et al. 2003. Herpetozoa 16:67–72). Adult male found in yard at residence.

Submitted by **KENNETH L. KRYSKO**, Florida Museum of Natural History, Dickinson Hall, Division of Herpetology, University of Florida, Gainesville, Florida 32611, USA; e-mail: kenneyk@flmnh.ufl.edu.

HEMIDACTYLUS GARNOTII (Indo-Pacific Gecko). USA: FLORIDA: Clay Co.: Keystone Heights, near Keystone Lake (29.78324°N, 82.032246°W; WGS84). 05 November 2008. B. K. Atkinson. Verified by M. A. Nickerson and K. L. Krysko. Florida Museum of Natural History (UF 153892). Juvenile gecko collected in private residence garden. New record for Clay County, extends the known range 17.3 km NE of the closest known specimen (UF 134315) in Bradford County, Florida (Krysko and Daniels 2005. Carib. J. Sci. 41[1]:28–36).

Submitted by **BENJAMIN K. ATKINSON** (e-mail: bka@ufl.edu), and **JAMES C. NIFONG (**e-mail: ncboy@ufl.edu), Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611, USA.

HEMIDACTYLUS MABOUIA (Wood Slave). HONDURAS: ISLAS DE LA BAHÍA: Isla de Guanaja, Savannah Bight (16.29078°N, 85.50300°W; WGS84), 14 m elev. 09 May 2007. Alexander Gutsche and James R. McCranie. Verified by Steve Gotte. USNM 570548–49. First record of this introduced species for Islas de la Bahía (McCranie et al. 2005. Amphibians & Reptiles of the Bay Islands and Cayos Cochinos, Honduras. Bibliomania!, Salt Lake City, Utah. viii + 210 pp.). The specimens were captured at night on concrete walls and a ceiling of the Savannah Hotel. The presence of subadults and adults indicate an established population. Fieldwork of A. Gutsche was supported by German Research Foundation (DFG 444 HON 111/1/07).

Submitted by **ALEXANDER GUTSCHE,** Humboldt-Universität zu Berlin, Institut für Biologie, Abteilung Sinnesbiologie,

Invalidenstr. 43, D-10115 Berlin, Germany (e-mail: alexander-gutsche@web.de); and **JAMES R. McCRANIE**, 10770 SW 164th Street, Miami, Florida 33157-2933, USA (e-mail: jmccrani@bellsouth.net).

HEMIDACTYLUS TURCICUS (Mediterranean Gecko). USA: LOUISIANA: Washington Parish: 1730 Sullivan Dr., Bogalusa, 3.5 km S of intersection of Highways 10 and 21 (30.75871ºN, 89.84551ºW; WGS 84). 17 July 2007. Beau B. Gregory and Aran C. Meyer. Verified by Jeff Boundy. LSUMZ 90434–90435. Two individuals captured on wall of building. First parish record (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana St. Univ. Press, Baton Rouge. 300 pp.).

Submitted by **BEAU B. GREGORY** and **ARAN C. MEYER**, Coastal and Nongame Resources Division, Louisiana Department of Wildlife and Fisheries, P.O. Box 98000, Baton Rouge, Louisiana 70898, USA.

SCELOPORUS JARROVII (Yarrow's Spiny Lizard). USA: NEW MEXICO: Grant Co.: Gila River, 2.0 km W, 0.8 km E Gila Hot Springs (33.17675°N, 108.20131°W, WGS84). 02 August 2006. Randy D. Jennings and Jan L. Frye. Two juveniles, one collected (43 mm SVL, WNMU 14779). Found on sycamore trunk by large rock outcrop near river. Vouchers from two additional sites were also collected (WNMU 14780, 14781) in 2007. All three locations are along 2.9 km of Gila River corridor; 0.8 air km separate two distant-most sites. All verified by C. W. Painter. Deposited in Western New Mexico University, Gila Natural History Collection. First verified collections in Grant County, an extension of ca. 160 km from known localities in neighboring Hidalgo County (Degenhardt 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.).

SQUAMATA – SNAKES

ARIZONA ELEGANS ELEGANS (Kansas Glossy Snake). USA: TEXAS: Irion Co.: 1.6 rd mi E of jct of TX SH163 on RM 2469 (31.2993ºN, 101.14035ºW). 2596 ft elev. 07 July 2007. M. S. Price, and N. M. Price. Verified by Travis J. LaDuc. Texas Natural History Collections (TNHC 66534 photo voucher). New county record and fills a distributional gap (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **MICHAEL S. PRICE**, San Angelo Nature Center, 7409 Knickerbocker Road, San Angelo, Texas 76904, USA; e-mail: michael.price@sanangelotexas.us.

BOGERTOPHIS SUBOCULARIS (Trans-Pecos Ratsnake). USA: TEXAS: Upton Co.: 1.3 rd mi N of U.S. Hwy 67 on CR 405 (31.1586333ºN, 102.20145ºW). 2692 ft elev. 12 June 1996. M. S. Price and J. Garza. Verified by Travis LaDuc. Texas Natural History Collections (TNHC 66555). New county record (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **MICHAEL S. PRICE,** San Angelo Nature Center, 7409 Knickerbocker Road, San Angelo, Texas 76904, USA; e-mail: michael.price@sanangelotexas.us.

CORALLUS CANINUS (Emerald Tree Boa) COLOMBIA: CALDAS: Municipio de Victoria, Vereda San Lorenzo (05.3394ºN, 74.9467ºW; WGS84), 800 m elev. 20 September 2008. J. D. Sánchez-L and A. Arias Alzate. Verifed by R. W. Henderson. Museo de Herpetología Universidad de Antioquia, Medellín, Colombia (MHUA 14625). The species has a wide distribution in the Amazon Basin occurring in Brazil, Peru, French Guiana, Suriname, Guyana, Venezuela, and Ecuador (Henderson 1993. Cat. Amer. Amp. Rept. 574:1–3). The only confirmed records for the species outside of the Amazon River basin are two documented vouchers from the Choco-Magdalena region in Colombia (Renjifo and Lundberg 1999. Anfibios y Reptiles de Urrá. Ed. Colina, Medellín, Colombia; Daza-R. and Henderson 2005. Herpetol. Rev. 36:338–339). This is first record for the Department of Caldas and extends the known distribution in the Magdalena River valley region ca. 248 km to the south.

LAMPROPELTIS CALLIGASTER CALLIGASTER (Prairie Kingsnake). USA: ARKANSAS: Searcy Co.: ca. 0.5 km W of jct. AR 14 and AR 263 (35.5925°N, 92.2458°W; NAD 83). 26 October 2008. M. B. Connior, I. Guenther. Verified by S. E. Trauth. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31273). Adult found DOR on AR 14. First county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. University of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **MATTHEW B. CONNIOR** (e-mail: matthew.connior@smail.astate.edu), and **IDUN GUENTHER**, Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA.

LAMPROPELTIS CALLIGASTER RHOMBOMACULATA (Mole Kingsnake). USA: ALABAMA: Chilton Co.: 9.0 km S of CR 25 on CR 73 (33.00685°N, 86.52074°W; WGS84). 25 May 2000. J. Burling. Verified by Joseph R. Mendelson III. University of Montevallo Collection of Vertebrates (UMCV-RS0083). Female with five eggs found dead on road. County record; fills a gap among Shelby, Bibb, and Coosa counties (Mount 1975. The Reptiles and Amphibians of Alabama. University of Alabama Press, Tuscaloosa. 347 pp.).Specimen was collected under Alabama Department of Conservation and Natural Resources collecting permit number 1044 (JWB).

Submitted by **JOHN W. BURLING[1]** and **JILL A. WICKNICK[2]**, Departments of Psychology[1] and Biology[2], University of Montevallo, Montevallo, Alabama 35115, USA (e-mail: wicknickja@montevallo.edu).

LAMPROPELTIS MEXICANA (Mexican Kingsnake). MEXICO: JALISCO: Sierra del Laurel near La Ciénega, along border with Aguascalientes (ca. 21.72970°N, 102.69890°W; WGS84), elev. 2435–2440 m. 26–27 July 2006. B. Alexander, R. W. Hansen, C. Heim, B. McGregor. Verified by David Lazcano. University of Texas at Arlington Digital Collection (UTADC 2602–2604, photo vouchers); Universidad Autónoma de Nuevo Leon (UANL, three specimens, uncatalogued). First records for Jalisco and ca. 33 km S of closest known locality from the Mesa Montoro region of Aguascalientes (Quintero-Díaz et al. 2001. Herpetol. Rev. 32:278). Snakes were collected under rocks or in crevices within rock outcrops that were surrounded by montane woodland dominated by oaks (*Quercus* spp.) and manzanita (*Arctostaphylos* sp.).

Scientific collecting permits were issued to us by SEMARNAT (OFICIO NUM.SGPA/DGVS/03382/06, OFICIO NUM.SGPA/DGVS/02100).

Submitted by **ROBERT W. HANSEN**, 16333 Deer Path Lane, Clovis, California 93619, USA (e-mail: rwh13@csufresno.edu); and **ROBERT W. BRYSON, JR.**, School of Life Sciences, University of Nevada-Las Vegas, 4505 Maryland Parkway, Las Vegas, Nevada 89154-4004, USA (e-mail: brysonjr@unlv.nevada.edu).

LAMPROPELTIS MEXICANA (Mexican Kingsnake). MEXICO: DURANGO: Municipality of Canatlán, ca. 30 km (air) WNW of Canatlán (24.5814167°N, 104.9354833°W; WGS 84), 2306 m elev. Summer 2007. Ron Savage. Verified by Carl Franklin. University of Texas Arlington Digital Collection (UTADC 2599, photo voucher). New municipality record, extending range northward by ca. 70 km (LACM 107230–31; Garstka 1982. Breviora 466:1–35) and brings *L. mexicana* to within 90 km of *L. alterna* on the eastern flank of the Sierra Madre Occidental (Ingrasci et al. 2008. Herpetol. Rev. 39:371–372). The snake was found in a rock crevice surrounded by

Madrean woodland, which appears to span the range gap between *L. alterna* and *L. mexicana* in unbroken fashion.

Submitted by **RON SAVAGE**, 609 Edmonston Street, Rockville, Maryland 20851, USA (e-mail: Ronsavage@yahoo.com); and **ROBERT W. HANSEN**, 16333 Deer Path Lane, Clovis, California 93619, USA (e-mail: rwh13@csufresno.edu).

LAMPROPELTIS TRIANGULUM TRIANGULUM (Eastern Milksnake). USA: GEORGIA: White Co.: Wildcat Mountain, 9.7 km WNW Helen (34.7270ºN, 83.8419ºW), 1064 m elev. 13 September 2008. Bryan Hudson and Carlos D. Camp. Verified by Kenney Krysko. Florida Museum of Natural History (UF 153761, photo voucher). Hatchling. New county record (Jensen et al. 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens. 575 pp.).

Submitted by **BRYAN HUDSON**, 101 Nancy Trail, Roswell, Georgia 30075, USA (e-mail: Yoitsbry142@aol.com); **CARLOS D. LIOPELTIS FRENATUS (Günther's Stripe-necked Snake). VIETNAM: THUA THIEN-HUE: Bach Ma. Collected before August 1998. Hoang Xuan Quang and students. Verified by Wolfgang Böhme. Zoologisches Forschungsmuseum Alexander Koenig, Bonn, Germany (ZFMK 83105). *Liopeltis frenatus* was previously reported in Vietnam from Lao Cai Province in the north and from the provinces of Quang Binh, Da Nang, and Gia Lai in central and southern Vietnam (Nguyen et al. 2005. A Checklist of Amphibians and Reptiles of Vietnam. Nha xuat ban nong nghiep, Hanoi, 180 pp.; Szyndlar and Nguyen 1996. The Snake 27:91–98; Orlov et al. 2003. Russian J. Herpetol. 10:217–240; Ziegler et al. 2007. Zootaxa 1493:1–40). Our finding represents the first record for Thua Thien-Hue Province, which borders Da Nang Province in the south. Besides coloration and pattern, the specimen has 15 smooth scale rows around midbody, 141 ventrals, 72 divided subcaudals, divided anal scale, seven supralabials (third and fourth in contact with eye), eight infralabials, single loreal, one preocular, and two postoculars that are characteristic of *L. frenatus*. The specimen is a female (SVL 340 mm; tail 128 mm) that contained four eggs of 25–28 mm length and 7–9 mm width.

Submitted by **THOMAS ZIEGLER**, Cologne Zoo, Riehler Str. 173, D-50735 Köln, Germany (e-mail: ziegler@koelnerzoo.de), and **HOANG XUAN QUANG**, University of Vinh, Nguyen Du Str., Vinh - Nghe An, S. R. Vietnam.

MICRURUS TENER (Texas Coralsnake). USA: TEXAS: Schleicher Co.: Eldorado, 7.0 rd mi SW (30.8270167ºN, 100.7056833ºW). 2433 ft elev. 07 April 2007. M. S. Price and N. M. Price. Verified by Travis J. LaDuc. Texas Natural History Collection (TNHC 66564). New county record (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **MICHAEL S. PRICE,** San Angelo Nature Center, 7409 Knickerbocker Road, San Angelo, Texas 76904, USA; e-mail: michael.price@sanangelotexas.us.

NERODIA SIPEDON (Northern Watersnake). USA: TEXAS: Dallas Co.: Dallas, White Rock Creek near northeast quadrant of Forest Lane and Hillcrest Road. 32.916482ºN, 96.776481ºW, 151 m. 28 April 2008. Specimens were collected from White Rock Creek from 1200–1545 h. Verified by Corey E. Roelke. Amphibian and Reptile Diversity Research Center at the University of Texas Arlington (UTA R- 55906–913). New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press. 421 pp.).

Submitted by **CARL J. FRANKLIN (**e-mail: Franklin@uta.edu), and **ERICK A. P. CATALÁN**, Amphibian and Reptile Diversity Research Center at the University of Texas Arlington, 501 S. Nedderman, Arlington, Texas 76019, USA.

PITUOPHIS CATENIFER SAYI (Bullsnake). USA: ILLINOIS: Kane Co.: Collected on property of a private residence in Geneva (41.900090 °N, 88.315087 °W; WGS84). 26 June 2008. Jace Robinson. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2008.20, photo voucher). New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **JACE W. ROBINSON**, Department of Biology, Harper College, Palatine, IL, 60067, USA; Department of Biological Sciences, Northern Illinois University, DeKalb, IL, 60115, USA; e-mail: jrobinso@harpercollege.edu.

PROTOBOTHROPS CORNUTUS (Smith's Horned Pit Viper). VIETNAM: HA GIANG: Khau Ca area (22.49º–22.51ºN, 105.05º–105.09ºE). October to November 2002. Photographed by Le Khac Quyet. Verified by Wolfgang Böhme. Zoologisches Forschungsmuseum Alexander Koenig, Bonn, Germany (ZFMK color slides 0210–11). Previously known from type locality "Fan-si-pan Mts., Tong-king" (Lai Chau/Lao Cai provinces) in northern Vietnam, as well as from localities in central Vietnam (Nghe An, Ha Tinh, Quang Binh, and possibly Thua Thien-Hue provinces: Ziegler and Herrmann 2002. Mitt. Zool. Ges. f. Arten u. Populationsschutz e.V. 18:24–26; Herrmann et al. 2004. Herpetologica 60:211–221; Orlov et al. 2003. Russian J. Herpetol. 10:217–240). New photographic reports from Ha Giang Province in northern Vietnam, close to border with Yunnan and Guangxi Zhuang Autonomous provinces (China), represent northernmost records in Vietnam, extending known distribution in northern Vietnam by ca. 200 km airline distance to NE. Besides coloration and pattern (brownish-black pattern on light brownish-gray head and body, reddish-brown tail tip), its distinctly raised, horn-like, enlarged supraocular scales are characteristic of *P. cornutus*. Both specimens were found between 1200–1500 h in sunny weather on tree trunk and in branches in limestone forest. Most recently, the species was recorded from China (Nanling Mountains), ca. 980 airline km distance from type locality (David et al. 2008. Asiatic Herpetol. Res. 11:17–23).

Submitted by **LE KHAC QUYET**, Fauna & Flora International—Vietnam Programme, IPO Box 78, 55 To Hien Thanh, Hanoi, S. R. Vietnam; and **THOMAS ZIEGLER**, Cologne Zoo, Riehler Str. 173, D-50735 Köln, Germany (e-mail: ziegler@koelnerzoo.de).

REGINA SEPTEMVITTATA (Queen Snake). USA: WISCONSIN: Rock Co.: Turtle Creek Watershed (42.59376821°N, 88.79786439°W; WGS84). Verified by Robert Hay. Illinois Natural History Survey (INHS 2008.i, photo voucher). New county record. Extends confirmed Wisconsin range ca. 6.4 km downstream from nearest confirmed Turtle Creek records (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum, 87 pp.; Wisconsin Herp Atlas, Univ. Wisc. Field Station, accessed Oct. 2008). One gravid female captured and photographed on 25 July 2008 (JMK and WPM). Complements two other unverified Rock County records: Carver's Rock Park off Turtle Creek, T2N, R14E, Sec. 27 (George Bachay, 1960) and Turtle Creek, T2N, R14E, Sec. 32 NE ¼ (Robert Parker Hodge, 1956) (Wisconsin Herp Atlas, *op. cit.*). Although this species prefers clear streams with rocky shores and substrates (e.g., Vogt 1981. Natural History of Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum, 205 pp.), this individual was found in a wet meadow, ca. 30 m from flowing water. The nearby stream was turbid, with muddy banks and likely a silt substrate. It is possible that the significant flooding that occurred in this area the month prior carried this individual downstream from known Walworth County sites into a habitat-type that was not normally preferred. The snake regurgitated a molted crayfish (species unidentifiable) while it was being manipulated for photographs.

RHADINOPHIS PRASINUS (Green Bush Ratsnake). VIETNAM: QUANG NAM: Dong Giang District, Macoih Commune, Axo Village. March 2004. Vu Ngoc Thanh. Zoological Museum, Vietnam National University Hanoi (VNUH 12.3.04–1). Verified by Wolfgang Böhme. *R. prasinus* (see Burbrink and Lawson 2007. Mol. Phyl. Evol. 43:173–189 for generic assignment) was previously known from a few provinces in northern Vietnam (Cao Bang, Lao Cai, Bac Kan, Thai Nguyen, and Vinh Phuc: Nguyen and Ho 1996. Danh luc bo sat va ech nhai Viet Nam. Ha Noi; Nguyen et al. 2005. A Checklist of Amphibians and Reptiles of Vietnam. Nha xuat ban nong nghiep, Hanoi, 180 pp.), as well as from Quang Binh and Gia Lai provinces in central and southern Vietnam (Orlov et al. 2003. Russian J. Herpetol. 10:217–240; Ziegler et al. 2007. Zootaxa 1493:1–40). In addition, Schulz 1996 (A Monograph of the Colubrid Snakes of the Genus *Elaphe* Fitzinger. Koeltz Scientific Books, Havlickuv Brod, 439 pp.) mentions two records for southern Vietnam "in the coastal buttresses of the northern Annam Highlands (Annam) and Plateau du Kontum." Thus, our finding represents the first record for Quang Nam Province in southern Vietnam. Specimen caught resting at noon on primary forest path at ca. 600 m elev. Besides coloration and pattern, 19 (dorsally keeled) scales across midbody, 209 ventrals, 107 divided subcaudals, undivided anal scale, nine supralabials (IV–VI in contact with eye), single loreal and preocular scale, and two postoculars are characteristic of *R. prasinus*. Specimen is female (SVL 800 mm; tail 275 mm), containing nine eggs of dimensions 31–39 mm x 16–19 mm.

Submitted by **VU NGOC THANH**, Vietnam National University, Hanoi, University of Science, Faculty of Biology, Department of Vertebrate Zoology, Zoological Museum, 334 Nguyen Trai Str., Thanh Xuan, Hanoi, S. R. Vietnam; and **THOMAS ZIEGLER**, Cologne Zoo, Riehler Str. 173, D-50735 Köln, Germany (e-mail: ziegler@koelnerzoo.de).

SISTRURUS MILIARIUS STRECKERI (Western Pigmy Rattlesnake). USA: ARKANSAS: Newton Co.: Found on County Road 78, E of AR 7. 28 September 2008. I. Guenther. Verified by S. E. Trauth. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31262). DOR. First county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univeristy of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **IDUN GUENTHER** and **MATTHEW B. CONNIOR (**e-mail: matthew.connior@smail.astate.edu), Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA.

SISTRURUS MILIARIUS STRECKERI (Western Pigmy Rattlesnake). USA: OKLAHOMA: Love Co.: Hickory Creek Wildlife Management Area (34.00464˚N, 97.06274˚W; WGS84). Collected by C. E. Roelke and C. L. Cox. Verified by C. J. Franklin. The University of Texas at Arlington Amphibian and Reptile Diversity Research Center (UTA R 56342). New county record (Webb 1970. Reptiles of Oklahoma. Univ. Oklahoma Press, Norman, Oklahoma. 370 pp; Distribution of Oklahoma Amphibians and Reptiles by Recorded Sightings [http://www.biosurvey.ou.edu/dokadesc.html], Accessed on 10/15/2008.) The specimen was found dead on main road leading through Wildlife Management Area. This record extends the known range of the species westward in Oklahoma, even though it is found slightly further west in Montague and Wise counties, Texas (Dixon 2000. Amphibians and Reptiles of Texas. Univ. Texas A&M, Univ. Press College Station. 421 pp.: Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. 437 pp.).

Submitted by **COREY E. ROELKE (**e-mail: croelke@uta.edu), and **CHRISTIAN L. COX,** University of Texas at Arlington, Department of Biology, 501 S. Nedderman Dr., Arlington, Texas 76019, USA.

STORERIA OCCIPITOMACULATA OCCIPITOMACULATA (Northern Red-bellied Snake). USA: IOWA: Chickasaw Co.: Newell Road 0.2 km N of State Hwy 24 (43.0616°N, 92.2797°W; WGS84). 04 October 2007. Terry J. VanDeWalle. Verified by James L. Christiansen. DOR specimen deposited in the Drake University Research Collection (DRUC 7298). New county record. Although species is known from a number of adjacent counties, this specimen fills a gap in the distributional data in this portion of the state (J. L. Christiansen, pers. comm.; http://www.herpnet.net/Iowa-Herpetology/). The closest record for this species found in the DRUC is from Bremer County 32.3 km to the south.

Submitted by **TERRY J. VANDEWALLE** (e-mail: tvandewalle@nrc-inc.net), and **STACEY J. CARLSON,** Natural Resources Consulting, Inc., 2300 Swan Lake Blvd., Suite 200, Independence, Iowa 50644, USA.

TANTILLA HOBARTSMITHI (Smith's Black-headed Snake). USA: TEXAS: Irion Co.: 2.2 air miles SW of Barnhart on CR311 (31.1134667ºN, 101.2040667ºW). 2600 ft elev. 03 April 2007. M. S. Price and J. T. Fisher. Verified by Travis LaDuc. Texas Natural History Collections (TNHC 68556, photo voucher). New county record (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **MICHAEL S. PRICE,** San Angelo Nature Center, 7409 Knickerbocker Road, San Angelo, Texas 76904, USA; e-mail: michael.price@sanangelotexas.us.

XENOPHOLIS UNDULATUS (Jensen's Ground Snake). BRAZIL: CEARÁ: Municipality of Ubajara, Ubajara National Park (03.840278°S, 40.907500°W; WGS84), 896 m elev. 09 September 2008. Coleção Instituto Butantan, São Paulo, Brazil (IBSP 76832). Municipality of Ubajara, Ubajara National Park (03.838346°S, 40.911467°W; WGS84), 829 m elev. 07 November 2008. IBSP 77110. Both specimens were collected by D. N. Lima, and verified by F. L. Franco. The species was recorded for Paraguay and Brazilian states of Goiás, Maranhão, Mato Grosso do Sul, Minas Gerais, Pará, Paraná, São Paulo, and Tocantins (Cunha and Nascimento 1993. Bol. Mus. Para. Emílio Goeldi, sér. Zool. 9[1]: 1–191; França et al. 2006. SNOMNH Occas. Pap. [17]:1–13). These new records represent an isolated population in the rainforests of Ibiapaba's plateau and also are the first report for the genus in Ceará state and from the Caatinga biome. Extends distribution ca. 770 km NE from Porto Franco municipality, Maranhão state, Brazil, and ca. 1220 km E from Carajás municipality, Pará state, Brazil (Cunha et al. 1985. Publ. Avul. Mus. Para. Emílio Goeldi 40:9–85).

**Corresponding author*

The herpetofauna of Colima, México, has not been thoroughly sampled. There have been only two published inventories for the state, but both appeared during the middle of the last century. Oliver (1937) reported on a collection from Colima and recorded 61 species of amphibians and reptiles from the state. Later, Duellman (1958) reported 85 non-marine species, and of those, 80 are still considered valid, although many have experienced taxonomic name changes. Since 1958, another 21 species were added to the state's list from a variety of publications revising specific groups, describing new taxa, or reporting new discoveries due to expanded field work. Therefore, 101 species of non-marine reptiles and amphibians were known to occur in Colima prior to the survey reported on herein.

Between January 2004 and October 2006, we surveyed the mainland herpetofauna from every municipality in the state of Colima and documented 94 of the 101 terrestrial species previously recorded. We did not sample marine species and three of the terrestrial forms are endemic to islands that were not visited. We also discovered 21 species that had never been reported from the state, including two salamanders, one caecilian, four anurans, five lizards, and nine snakes. Although we sampled every major habitat present on mainland Colima, our efforts were primarily focused in four areas: 1) tropical deciduous forest and tropical thorn scrub in the Municipality of Ixtlahuacán; 2) tropical thorn scrub, tropical deciduous forest, tropical semi-deciduous forest, and mixed tropical deciduous/oak woodland along México Hwy. 98 between the cities of Colima and Manzanillo, in the Municipalities of Comala, Manzanillo, Minatitlán, and Villa de Álvarez; 3) pine-oak woodland and cloud forest in the Sierra de Manantlán, Municipality of Minatitlán; and 4) tropical thorn scrub and mixed mesquite grassland/tropical thorn scrub at higher elevations above the city of Colima in the Municipalities of Colima, Comala, Cuauhtemoc, and Villa de Álvarez. See Fig.

1 for a map depicting collecting localities for individuals listed in the species accounts. Those accounts may include only one voucher for a larger series observed within a given locality. All four authors were involved in collecting voucher specimens and taking digital photographs. Preserved specimens were deposited in the Museo de Zoología, Facultad de Cinecias (MZFC) and verifying photographs were placed in the Digital Collection, University of Texas at Arlington (UTADC). Vouchers deposited in MZFC were verified by Edmundo Perez-Ramos and those placed in UTADC by Fernando Mendoza-Quijano. Coordinates and elevations were taken with a GPS device using map datum WGS84. New state records for the 21 species of amphibians and reptiles from Colima are as follows.

Anura

Dendropsophus sartori (Taylor's Yellow Treefrog). Municipality of Colima: 1.6 km E of México Hwy. 110 on road to Tepames (19.105727°N, 103.405559°W), 476 m elev. 6 July 2004. UTADC 1020. Municipality of Manzanillo: 3 km NE Tepehuajes on México Hwy. 98 446 m elev. (19.153846°N, 104.101999°W), 446 m elev. 28 June 2004. UTADC 1021. These records fill a significant gap in the known distribution of this species between the Chamela-Cuixmala region of southwestern Jalisco and the coast of central Guerrero (Duellman 2001). Both samples were males found calling in flooded agricultural fields surrounded by tropical deciduous forest.

Hyla arenicolor (Canyon Treefrog). Municipality of Colima: 5 km (by air) SW of Tepames (19.0816°N, 103.666°W) 870 m elev. 7 January 2005. UTADC 1018. This record is a range extension of ca. 90 km S of the two nearest published records, 4 km NE Ciudad Guzman, Jalisco, and 14.4 km NE Union de Tula, Jalisco (Duellman 2001). Numerous males were found calling from rocks next to an intermittent stream in tropical deciduous forest.

Hyla eximia (Mountain Treefrog). Municipality of Villa de Alvarez: El Naranjal (19.243741°N, 103.392046°W), 1443 m elev. 23 September 2006. UTADC 1019. The record represents a range extension of 40 km SW of the closest known locality in southern Jalisco (Duellman 2001). Frogs were found calling in a flooded field within an ecotone between tropical thorn scrub and mesquite grassland.

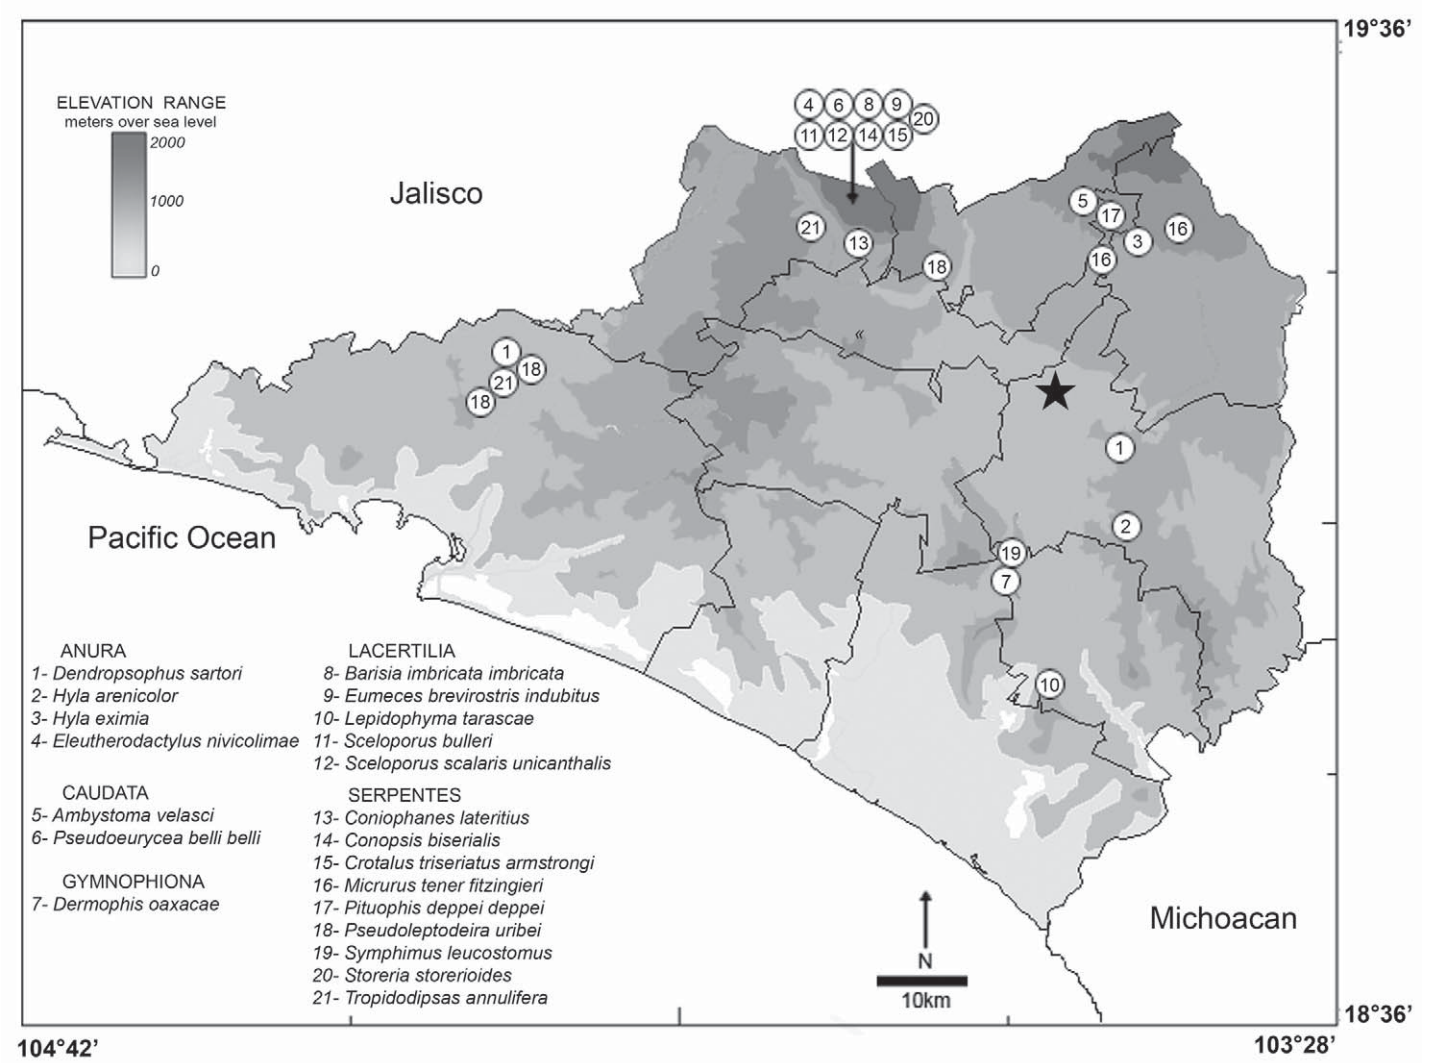

FIG. 1. Map of Colima, México showing collection localities reported in the text and a list of species collected from those localities. The star indicates the city of Colima.

Eleutherodactylus nivicolimae (Nevado de Colima Chirping Frog). Municipality of Minatitlán: Sierra Manantlán: 2.3 km SW (by road) of El Terrero (19.261686°N, 103.573144°W), 2040 m elev. 11 July 2004. UTADC 1033. This record represents a range extension of approximately 46 Km SW of the closest known localities on Nevado de Colima, in Jalisco (Dixon and Webb 1966). The frog was calling at 2200 h from the base of a tree in oak forest.

Caudata

Ambystoma velasci (Plateau Tiger Salamander). Municipality of Comala: 13 km NNE of Comala (19.251511°N, 103.405721°W), 1520 m elev. 9 February 2007. UTADC 1037. This record is a range extension of 60 km S from the closest known locality 2.68 km E Tapalpa, Jalisco (McKnight and Shaffer 1997). The series is composed of larvae captured in a flooded grassy field, two of which were kept in captivity until metamorphosis to facilitate identification, and then released. Surrounding vegetation was a mix of tropical thorn scrub and mesquite grassland.

Pseudoeurycea bellii bellii (Bell's False Brook Salamander). Municipality of Minatitlán: 2.5 km SE of El Terrero (19.25528°N, 103.54510°W), 2164 m elev. 11 July 2004. MZFC19769. This locality is a range extension of ca. 8 km SE of El Tepeixtle, Tolimán, Jalisco, which was initially recorded erroneously from Colima by Mendoza-Quijano et al. (1995) The salamander was found under a log in cloud forest. It is noteworthy that the species is presently abundant at this site.

Gymnophiona

Dermophis oaxacae (Oaxacan Caecilian). Municipality of Ixtlahuacan: 2.8 km (by road) SW of La Salada (19.01816°N, 103.47446°W), 297 m elev. 24 June 2006. UTADC 1016. This record represents a range extension of ca. 150 km S from the closest reported locality, 50 NE Autlan, Jalisco (Savage & Wake 2001). The specimen was found AOR on a rainy night in tropical deciduous forest.

Lacertilia

Barisia imbricata imbricata (Imbricate Alligator Lizard). Municipality of Minatitlán: Sierra de Manantlán: 2.5 km SE of El Terrero (19.255454°N, 103.56444°W), 2200 m elev. 15 August 2004. UTADC 1012. This record represents a range extension of ca. 37 km ESE from the nearest reported locality on the Sierra de Manantlán in adjacent Jalisco (Guillette and Smith 1982). Several juveniles and the reported adult were seen crawling in leaf litter on a hillside covered by oak woodland.

Eumeces bevirostris indubitus (Mexican Shortnose Skink). Municipality of Minatitlán: Sierra de Manantlán: El Terrero, 2183 m elev. (19.2540°N, 103.9388889°W). 11 July 2004. UTADC 1017. This record represents a 43 km SW range extension from the nearest reported locality near Atenquique, Jalisco (Dixon 1969). Individuals of the species were commonly observed at the site in pine-oak woodland under rocks and in leaf litter.

Lepidophyma tarascae (Tarascan Tropical Night Lizard). Municipality of Ixtlahuacán: 1 km NW of San Gabriel (18.55339°N, 103.44016°W), 538 m elev. 3 July 2005. UTADC 1022. This record extends known distribution 95 km WNW from closest reported locality in the Municipality of Aguililla, Michoacán (Guzmán-Villa et al. 1998). The specimen was found at dusk in a crack of a limestone wall in tropical deciduous forest, which is the same plant formation reported by Bezy et. al. (1982) at the type locality. Guzmán-Villa et al. (1998) erroneously suggested that the species is restricted to pine-oak woodland.

Sceloporus bulleri (Buller's Spiny Lizard). Municipality of Minatitlán: Sierra de Manantlán: 1.7 km SW of El Terrero (19.2604°N, 103.5740°W), 2098 m elev. 11 July 2004. UTADC 1029. This record represents a range extension of ca. 65 km SE of the closest know locality in SW Jalisco (Webb 1967). The species was commonly observed on dead trees and under rocks at this site, which is situated in pine-oak woodland.

Sceloporus scalaris unicanthalis (Smith's Bunch Grass Lizard). Municipality of Minatitlán: Sierra de Manantlán: 3.5 km SE El Terrero (19.252494°N, 103.543354°W), 2160 m elev. UTADC 1030. 3 August 2005. This record represents a range extension of ca. 40 Km SW of other known localities in Jalisco on Nevado de Colima and vicinity of Ciudad Guzmán (Smith et. al. 1997). The lizard was found among bunch grass in an open mountain meadow surrounded by pine-oak woodland.

Serpentes

Coniophanes lateritius (Cope's Stripeless Snake). Municipality of Minatitlán: 6.4 km W of junction of México Hwy. 98 and road to El Sauz (19.225443°N, 103.57704°W), 750 m elev. 9 August 2005. UTADC 1013. This record represents a SE range extension of 110 km from the nearest reported locality in Jalisco (Ponce-Campos & Smith 2001). The specimen was found AOR at ca. 1500 h in tropical deciduous forest.

Conopsis biserialis (Two-lined Mexican Earth Snake). Municipality of Minatitlán: 2.5 km SE of El Terrero (19.135838°N, 104.12384°W), 2200 m elev. 15 August 2004. UTADC 1014. This record represents a SW range extension of 40 km from the nearest locality on Nevado de Colima in Jalisco (Goyenechea & Flores-Villela 2006). Numerous other samples were found under rocks in pine-oak forest.

Crotalus triseriatus armstrongi (Armstrong's Dusky Rattlesnake). Municipality of Minatitlán: Sierra de Manantlán: 1.7 km SW El Terrero (19.2604°N, 103.5740°W), 2098 m elev. 15 August 2004. UTADC 1015. This expected record extends the known range ca. 12 km N of other localities on the Serra de Manantlán in adjacent Jalisco (Campbell and Lamar 2004). The snake was found crossing a dirt road at 1900 h in oak forest. It is noteworthy to mention that the species was locally abundant in the vicinity of this site, as over 30 individuals have been found there during the past three years.

Micrurus tener fitzingeri (Fitzinger's Coral Snake). Municipality of Cuauhtémoc: vicinity of Montitlán, 30 km (airline) NNW of Colima, (19.244323°N, 103.361477°W), 1480 m elev. 13 February 2004. MZFC 19743. Municipality of Villa de Alvarez: vicinity of El Carrizal, 17.5 km (airline) N of Colima (19.233248°N, 103.402168°W), 1291 m elev. 23 November 2005. MZFC 19746. These records represent a 350 km range extension W of the closest known localities in western Queretaro (Campbell and Lamar 2004). Both snakes were found in tropical thorn scrub.

Pituophis deppei deppei (Mexican Bullsnake). Municipality of Comala: Laguna Carrizalillos: 19.5 km N of Colima (19.244553°N, 103.402534°W), 1492 m elev. 3 August 2005. UTADC 1026. This record represents a range extension of 60 km S from the nearest known locality at Tapalpa, Jalisco (Campbell 1979). The area is in an ecotone between tropical thorn scrub and oak forest.

Pseudoleptodeira uribei (Uribe's False Cat-eyed Snake). Municipality of Comala: 4 km SW of Juluapan, on México Hwy. 98 (19.182966°N, 103.511855°W), 494 m elev. 14 May 2004. MZFC 19752. Municipality of Manzanillo: 2 km SW Tepehuajes, on México Hwy. 98 (19.181829°N, 103.513089°W), 482 m elev. 8 May 2004. MZFC 19775. 3 km NE Tepehuajes, on México Hwy. 98 (19.152967°N, 104.101939°W), 453 m elev. 29 June 2004. UTADC 1028. These records help fill a 190 km distributional gap between Estación de Biologia Chamela, Jalisco, the type locality (Ramirez-Bautista and Smith 1992), and Ejido Maquili, Michoacán (Mijangos et al. 2007). All three specimens were found DOR in tropical deciduous forest.

Storeria storerioides (Mexican Brown Snake). Municipality of Minatitlán: Sierra de Manantlán: 2.5 km SE of El Terrero (19.255454°N, 103.56444°W), 2200 m elev. 11 June 2004. UTADC 1031. This record fills a distributional gap between localities at Chinicuila, Michoacán (Ponce-Campos et al. 2003) and Tapalpa, Jalisco (Campbell 1979). The snake was found under leaf litter in oak forest.

Symphimus leucostomus (Isthmian White-lipped Snake). Municipality of Ixtlahuacán: 1.7 km NE of La Salada (19.0653306°N, 103.7819833°W), 448 m elev. 11 October 2004. UTADC 1032. This record fills a distributional gap between 14.2 km S of La Huerta, Jalisco (Rossman and Shaefer 1974) and 23 km NW of Punta San Telmo, Michoacán (Alvarez and Diaz-Pardo 1982). The snake was found DOR in tropical deciduous forest.

Tropidodipsas annulifera (Western Snailsucker). Municipality of Minatitlán: 1.5 km W of exit to El Sauz on México Hwy. 98 (19.251908°N, 103.594542°W), 1042 m elev. 28 May 2004. UTADC 1034. Municipality of Manzanillo: 1 km SW Tepeguajes (Puertecito de Lajas) on México Hwy. 98 (19.135838°N, 104.12384°W), 430 m elev. 11 September 2006. UTADC 1035. These records fill a large distributional gap between SW Jalisco and central Guerrero (Kofron 1988). Both specimens were found DOR in tropical deciduous forest.

Acknowledgments.—We thank Jason M. Jones, Chris Rodriguez, the late Fernando Mendoza-Quijano, Edmundo Perez-Ramos, Uri Garcia, Eric Smith, and Jonathan Campbell for their help with this project; Joseph T. Collins for kindly reviewing the manuscript; and Ginny N. Weatherman and the University of Kansas library staff for their valuable assistance.

Malformed Frogs, the Collapse of Aquatic Ecosystems, by Michael Lannoo. 2008. University of California Press, Berkeley (www.ucpress.edu). Hardcover. xvi + 270 pp. US $65.00. ISBN 978-0-520-25588-3.

STANLEY K. SESSIONS
Department of Biology, Hartwick College
Oneonta, New York 13820, USA
e-mail: sessionss@hartwick.edu

I remember the phone call from an official at the regional EPA research lab in Duluth, Minnesota. A group of students from a charter school had found some abnormal frogs during a field trip to a local wetland. The frogs exhibited mainly hind limb deformities, including twisted, missing, or even duplicated hind limbs. The teacher immediately realized that this was a great opportunity to get her students involved in a genuine scientific puzzle, and they reported their discovery to the Minnesota Pollution Control Agency (MPCA). The MPCA helped the kids put together a web page concerning deformed amphibians and what it possibly signified. The web page mentioned something about chemical pollution (who wouldn't think of that?), which generated a firestorm in the media. Soon stories began appearing in major newspapers about a "froggy love canal" with the implication that there might be some contaminant in Minnesota ground water causing thalidomide-like limb "malformations" and worse. I can easily imagine a Minnesota farmer sitting down to breakfast, picking up the newspaper and spitting out his coffee as he reads the headlines: Minnesota ground water may cause birth defects. Soon, state authorities were distributing bottled water to all who asked for it. Inevitably, the US Environmental Protection Agency would become involved. The EPA official called me because I had published a paper on deformed amphibians five years earlier providing an "explanation" for the deformities, and he invited me to an emergency deformed frog workshop at the EPA lab in Duluth.

The Duluth workshop was infused with a sense of urgency and excitement. I watched with amazement as slide after slide of frogs with astonishing deformities elicited audible gasps from the audience. Multilegged frogs drew the most attention as the oddest deformities, and soon became the "poster child" for deformed frogs. My presentation focused on the research I had done with colleague Steve Ruth in California on populations of deformed Pacific Treefrogs and Long-toed Salamanders, most of which had hind limb duplications but a wide range of other deformities as well, including missing limbs (Sessions and Ruth 1990). We showed that the deformities were caused by a parasitic flatworm (trematode) that disrupts limb development in young tadpoles. My intention was to present "the parasite hypothesis" as the one to exclude before searching for more elusive and (in my view) less likely causes such as chemical pollution. In fact, chemical pollution seemed very unlikely as a cause for multi-limbed frogs in particular, since toxic chemicals are far more likely to kill cells and halt limb development than to induce cells to build extra structures. To my amazement, my presentation seemed to help divide the group of researchers into two opposing camps, setting the stage for a decade of controversy: those who favored the chemical pollution hypothesis, and those who favored the parasite hypothesis.

It was at the meeting in Duluth that I first met Mike Lannoo, a well-known and highly respected herpetologist from the Indiana University School of Medicine. A somewhat reserved man, Lannoo played the role of a sort of deformed frog diplomat. Impressed with the strength of the parasite evidence (in fact, he was responsible for my being invited to the workshop), he also saw merit in other hypotheses, including chemical pollution, UV-B radiation, and even predation. In the ensuing controversy and associated media craziness and follow-up workshops and conferences, Mike continued to keep a relatively low profile, focusing his energies on editing multi-authored compendia on declining and deformed amphibians. His "behind the scenes" role is described in William Souder's book "A Plague of Frogs" (Souder 2000). Lannoo patiently waited 10 years for all the fuss to die down before coming out with his own definitive statement about deformed amphibians: *Malformed Frogs, the Collapse of Aquatic Ecosystems*.

Lannoo's book is a solid, handsome little volume, 23.5 cm tall, 16 cm wide, and 2 cm thick, with excellent quality paper, narrow margins, and an attractive, easy-to-read font. Most of the illustrations are black and white and of excellent quality, as are the few pages of beautiful color plates. Physically, it is a high quality book, as expected from the University of California Press (even if, at US $65.00, a bit on the expensive side). After a brief introduction, personal preface and acknowledgment sections, the contents of the book are sorted into seven chapters. The first chapter addresses the issue of what is an amphibian "malformation." Beginning with a quote about symmetry (as a sign of health), Lannoo defines malformation as "bad form" and "unintended" lack of symmetry that arises through one of three mechanisms: genetic flaws, epigenetic perturbation of gene expression, and trauma due to injury or disease. After a brief discussion of each of these mechanisms, Lannoo concludes that the most likely cause is "epigenetic disturbance of gene expression." Lannoo then presents evidence that most malformations involve anurans rather than urodeles. This chapter also presents important background information including a primer on frog skeletal anatomy and limb development, with some brief comments on jaw and eye development, and ends with some comments about when in development certain malformations are likely to arise.

The second chapter covers "malformed frog types" and presents the main kinds of malformations seen including high quality x-ray photographs of over 50 specimens representing the different types. A handy-dandy table provides a description of each of the types, most of which are designated by medical terminology; for example, *microphthalmia* (small eye), *amelia* (missing limb),

taumelia (bent bone), *polymelia* (complete extra limb), and so forth. Some malformations do not have a Latinized medicinal moniker (e.g. "bloated body"). Some of these main types can be broken down into subtypes, for example *unilateral amelia* (too few hind limbs) or *unilateral hemimelia* (short limb on one side). Most of the examples are *Rana pipiens*, but a few other species are included, such as *Acris crepitans* and *Bufo americanus*. The examples are meticulously assembled and presented along with collection locality, collectors, and sometimes a Field Museum specimen number.

Chapter Three focuses on "hotspot" localities, mostly in Minnesota and nearby regions in the Midwest that have yielded a large number, and especially percentage, of malformed amphibians. Here we are presented with a map, showing the overall distribution of the hotspots in Minnesota, and then each hotspot locality (designated with an abbreviation for convenient cross-referencing) is described with an accompanying photograph of the site. The entries include a brief description of the physical aspects, some of the major vegetation present, what types of deformities were found at each one, and how many animals were sampled. In most cases, brief mention is made of any other obvious organisms encountered at the locality, including insects, snails, crustaceans, fishes, and other species of amphibians.

Chapter Four ("Causes") reviews the main causes of amphibian malformations that have been proposed or confirmed over the years. Here Lannoo first divides the causes into two broad categories (following Ouellet 2000): Natural causes and Manmade causes. Natural causes include wounding (failed predation attempts), fish excrement (involving the mysterious "*anomalie P*"; you'll have to read the book and/or Ouellet 2000), crowding, sweet pea extracts (lathyrogens), nutritional deficiencies, UV-B radiation, disease, temperature extremes, genetics, and parasitic cysts. Manmade causes include acidification, radioactive contamination, ozone depletion (UV-B radiation), heavy metals, retinoids, agricultural chemicals (e.g., pesticides), and other chemicals (especially xenobiotics). The brief (four page) descriptive list of causes in Chapter Four is followed by two of the most interesting sections in the book: "synergisms and neutralizations," discussing the possible (probable) interaction of multiple factors in the generation of malformations, and especially "determining cause from malformation type: the search for morphological signatures" in which we are assured that there are, as yet, no morphological signatures in the deformities that point to a particular cause.

Finally we come to probably the most important (or, at 65 pages, at least the largest) chapter of the whole book: Chapter Five, which is devoted to resolutions. The chapter begins with a brief and somewhat scolding diatribe about "bitter personality clashes" that warped the scientific process of discovery into one of competition and simplification, thereby interfering in a resolution of the problem, and warnings about falling into the trap of adaptationist ("just so") thinking (I get a slap on the hand here). Most of the rest of the chapter is devoted to a "deconstruction" of the major hypotheses presented to explain amphibian malformations, and ends with an overall summary of where we stand, in the form of Lannoo's answers to Frequently Asked Questions about amphibian malformations.

Chapter Six covers human malformations and causes (which I mostly skipped), and then we come to the last chapter, Chapter Seven: "Solutions." If Chapter Five was the pièce de résistance of the book, Chapter Seven appears to be the raison d'etre. After another brief diatribe, scolding fellow researchers for tending to reduce the problem to one or two main causes, Lannoo comes, finally, to his shocker conclusion (presented as a kind of unfunny joke): The solution to the malformed frog phenomenon is largely independent of specific cause. Here is the reasoning: After all is said and done, given the complexity of wetland ecology and environmental science, including parasites, predators, UV-B radiation, and various kinds of chemical pollution, it is obviously unlikely that there is a single cause for all malformations in natural populations of amphibians. Instead, the malformed frog problem largely consists of local, site-specific issues. The important thing, according to Lannoo, is that we identify the correct *solution*, and luckily we already know what that is! All vectors point towards one gigantic ultimate problem: general environmental degradation, in this case, collapse of wetland ecosystems. Thus the solution is obvious: ecosystem remediation.

In terms of overall organization of the book, I like it with one exception: Lannoo references his comments with notes that are listed numerically at the end of the book. Thus, to look up a footnote or citation, you must flip to the back of the book and search around for the correct chapter and then find the corresponding number. Because some of the entries contain a large number of references, this is more difficult that it sounds. I found this to be a nuisance. Many will appreciate a section at the end of the book called "species affected," which lists all known species of amphibians with those involved in reported deformities indicated in bold.

My overall take of this book is that it is a very useful summary of the most important issues and research involved in the problem of deformed amphibians. It should be on every herpetologist's bookshelf, and is also of use to anyone who is interested in environmental issues and controversies, and even how science works in the context of such human foibles as competition for attention and grants. Having said that, and being intimately involved in some of the controversy and privy to some of the fascinating stories that have emerged (see Souder's book, *A Plague of Frogs*, for a taste), I do take issue with some of Lannoo's conclusions. Here I will give just a few main examples.

The very first chapter should have served as a warning for me that working my way through the rest of the book was going to involve a struggle with semantics and specific terminology. Definitions are important, and anyone who has kept track of the deformed frog controversy has noticed that some people refer to the abnormalities as "malformations" while others refer to them as "deformities." In the world of medical terminology, the difference in meaning between these two terms is highly significant. Malformation implies an *intrinsic* developmental defect of developing tissues (Winter et al. 1988; MedicineNet.com 2008) whereas deformity refers to *extrinsic* (environmental) factors disrupting the development of *otherwise normal* tissues. Because all of the suggested and known causes of morphological abnormalities in amphibians involve extrinsic factors (e.g., parasites) disrupting the development of otherwise normal tissues, the more precise term for these abnormalities is "deformity."

The question is why does Lannoo use the term malformation rather than deformity? My opinion is that in the world of deformed amphibian research, these terms have become ideological, or

politicized, and the term malformation is usually used to imply disruption of biochemical processes in developing systems, such as endocrine disruption. In this sense, malformation implies disruption of biochemical signaling pathways, for example in the developing limb. Scary stuff indeed! So much is now known about the biochemistry and developmental genetics of limb development that it is easy to construct a detailed scenario by which small biochemical perturbations (via retinoids, for example) could generate monstrocities. One problem here is that I think Lannoo has a very simplistic (deterministic) view of limb development, as exemplified by his statement that "…developmental biology is largely a chemical phenomenon" (p. 193). In actuality, developmental biology is largely a *cellular* phenomenon, and this is critical in understanding how various kinds of deformities are generated. For example, it is only by understanding limb pattern formation as the outcome of interacting cells in an undifferentiated limb bud that you can fully appreciate how parasites can generate massive limb deformities using nothing but mechanical perturbation (Stopper et al. 2002).

Likewise, Lannoo does not seem to understand *amphibian* limb development, specifically in anurans, and this colors his assessment of various cause hypotheses. A dirty little secret (just emerging in recent years) of the deformed frog controversy is that multilegged frogs, the oddest-looking deformities which (understandably) became the poster child of the deformed frog issue (featured in several articles and on the covers of several books) actually represent a small minority of reported cases of deformed amphibians, at least in number of reported hotspots. By far the most common deformities are frogs with *missing* hind limbs and missing hind limb segments and, while less dramatic looking than multilegged frogs, these have turned out to be far more difficult to explain. Anyone who picks up a limbless frog should first think of predation as the most likely explanation. This is Ocam's razor at work. However, Lannoo spends a considerable amount of book space debunking the role of predation, based mainly (as far as I can tell) on assumptions and logical inferences derived from various anatomical and morphological characteristics of deformed frog specimens (ironic given his previous debunking of "morphological signatures"). For example, he sees no obvious signs of wounding or wound repair, he sees pigment malformations in most of the specimens, he sees damaged limb girdles as well as limbs, he finds no evidence of likely predators, etc. Most of these objections are invalidated by one key characteristic of anuran limb development of which Lannoo appears to be unaware: Regenerative decline (Muneoka et al. 1986). Young tadpoles with early limb buds can completely regenerate their limbs, but this ability gradually diminishes to zero as they approach metamorphosis and the limbs complete their development. At intermediate stages, amputation of a limb results in a range of incomplete limb development represented by a panoply of idiosyncratic abnormalities including bent bones, cellular accumulations, cartilaginous spikes, and pigment abnormalities. I feel that this is a major omission in the book and a serious flaw in Lannoo's overall analysis of the most common types of deformed amphibians.

To understand how limb development works you need to think like a developmental biologist, who is used to contemplating the cellular basis of pattern formation and morphogenesis in four dimensions, and small things early on having big final ramifications. Developmental thinking is necessary to appreciate how trematode cysts, located at the base of fully developed limbs, could be responsible for massive deformities located distally. I found the lack of developmental thinking in the book frustrating, because it is so necessary for understanding how various deformities can arise from disparate causes, but not from others. I feel that this is how Lannoo could assert the absence of "morphological signatures" that would point to particular causes. For example, over a century of research in limb development has shown, via simple grafting experiments, that mechanical disruption of the spatial organization of cells in a developing or regenerating amphibian limb is all that parasite cysts need to do to cause the outgrowth of different kinds of mirror-image limb duplications (French et al. 1971). Retinoids can cause a subset of these, but not all of them (Sessions et al. 1999). On the other hand, a true signature of retinoids is a proximal-distal duplication (e.g., two elbows; Bryant and Gardiner 1992). Likewise, the presence of a cartilaginous bump or spike on the end of a limb stump indicates traumatic amputation near the end of regenerative decline (late tadpole stages; Muneoka et al. 1986). Thus, in Chapter 2 where deformed frog types are described and illustrated, I was able to identify the *most likely* causes of the deformities in over 80% of the cases. Out of a total of 63 specimens, 23 were almost certainly parasite-induced and 28 were almost certainly trauma-induced. Nine of the remainder appeared to be trauma, one appeared to be parasite-induced, and only two of them seemed completely ambiguous. Of course, the most important morphological signature of all is the fact that the vast majority of deformities involve the hind limbs, with the rest of the frog (including the front limbs) appearing perfectly normal.

Finally, I cannot agree with Lannoo's conclusion that wetland ecosystem remediation is the solution to the problem of deformed amphibians regardless of the specific causes. What if it turns out (as seems likely to me) that parasites and predation together account for the vast majority of deformities (or "malformations") in natural populations of amphibians? As Lannoo's parasitologist friend, the late Dan Sutherland (to whom the book is dedicated), pointed out to him (and to me), parasites are even more sensitive to environmental pollution than amphibians….. so we should worry when the parasites disappear! Likewise, predator diversity is, if anything, negatively affected by habitat degradation. So if we follow Lannoo's advice (which seems like good advice under any circumstances), ignoring the causes of amphibian deformities and focusing on *the solution* (wetland remediation), we might actually expect an *increase* in the incidence of amphibian deformities! I call this the "perverse hypothesis."

CÉSAR L. BARRIO-AMORÓS
Fundación Andígena, Apartado Postal 210, 5101-A Mérida, Venezuela
e-mail: atelopus@andigena.org

Lovers of Neotropical turtles and crocodilians are lucky. This new book fills the enormous vacuum of information that exists with respect to these two orders, gathering information that was previously scattered in many publications, some with quite limited circulation. Until now, the most comprehensive books that treated these animals were Pritchard and Trebbau's (1984) masterpiece, *The Turtles of Venezuela*, (required reading for anyone interested in any aspect of South American turtles, not just Venezuelan ones) and Federico Medem's two classics (1981, 1983) about Colombian and South American crocodilians, respectively. Those interested in the last quarter century of new data, however, have had to search through mountains of diverse primary sources and regional and national publications.

The work of the multiple authors of this book, supported by three formidable illustrators (Stephen Nash, César Landazábal, and Marco Rada), and an endless list of collaborators, has yielded an extraordinary result that will certainly become a herpetological classic both because of the quality of information presented and because of its fine illustrations. The text is entirely in Spanish but, as I have previously argued (Barrio-Amorós 2006a, b), anyone with a serious interest in working with Neotropical species should master Spanish, at least to the level of competent reading comprehension.

The book, of small size (20 x 12 cm) and ideally suited for the field, is unusually beautiful, showing on its front cover an illustration of the rare species *Mesoclemmys dahli*, and on its back the threatened Orinoco Crocodile, along with the logos of sponsoring institutions. Two maps of South America, one physiographic, another showing major vegetation types, are on the inside covers. The book is dedicated to the Latvian herpetologist Federico Medem, who arrived in Colombia after the Second World War and became the most important investigator on turtles and crocodiles of that country. He died in 1984, leaving the most comprehensive information to date on the Colombian species of these two orders. Reminiscences by Russell Mittermeier (current president of Conservation International) and Anders Rhodin (president of the group of the IUCN Terrestrial and Freshwater Turtle Specialist Group), both of whom were influenced by Medem in their youth, provide a suitable tribute. This is followed by a foreword, brief resumés of the authors and illustrators, acknowledgments, and a table of contents.

The introduction highlights aspects of the conservation of chelonians and crocodilians in the region. A guide for handling marine turtles injured by fishing hooks, which has also been published as a separate pamphlet, is included in this section. The introduction to the general characteristics of chelonians is extremely complete and well-illustrated. There is also a section on how to record field data (valid for all types of vertebrates), how to mark shells, how to take different measurements, how to capture turtles using different methods, etc. There are very well illustrated keys at both the family and species level. The text for each species account is complete and accompanied by color photos and/or illustrations of the animal and very accurate distribution maps. In some cases, however, the origin of the photographed specimen is not noted.

The comparable section dealing with the Crocodylia is equally valuable, with extensive and informative text, high quality photos and illustrations, useful keys (including one for eye shines and another for skins), and many other features.

Following the main text a further 70 plates with multiple photos and illustrations each are provided. These show, amongst other things, sexual, ontogenetic, and geographic variation of the included species. It would have seemed preferable to have these illustrations placed in the relevant sections of text, particularly since the book has color throughout anyway, but clustered as they are they do permit easy visual comparisons of similar or related species.

A glossary with the most important terms, a bibliography, and an index to species complete the book. The bibliography, although useful, is not as complete as it might be and some references are lacking although, based on the updated information presented in the text, it seems they were consulted (e.g., Barrio 2001; Barrio-Amorós and Manrique 2006).

There are a number of seeming inconsistencies in the book, but these do not detract significantly from the work as a whole. The title, although correct, may surprise readers not familiar with the Neotropics, since it may seems that the species are restricted to the countries usually understood as Andean. These, for most of the people, are only Bolivia, Peru and Ecuador. The word "Andean" may also be surprising, since no turtle or crocodile species live in the Andes proper (the highest are found in the Andean foothills at no more than 1000 m). However, the tropical Andean countries also include Venezuela and Colombia (but exclude Argentina and Chile, which are Andean but not tropical). So the context is that of the species inhabiting these five countries, and extending the information to other countries where the same species also occur — although these are not Andean (Brazil, Paraguay, the Guianas, Trinidad and Tobago). The presence, for example, of *Mesoclemmys vanderhaegei* in the book is due to the possibility that it may occur in Bolivia. The treatment of Galapagos tortoises in a book with this title may also seem out of place, but of course, the islands belong to Ecuador. The map for *Chelus fimbriatus* is actually correct, but a spot in the southern part of Lake Maracaibo in Venezuela, represents a reported, but unconfirmed record that might have been more appropriately designated with a question mark. Another point to highlight is that the section of common and indigenous names, which is often incomplete, gives the common names in use Colombia, since the book was originally going to be dedicated only to that country. In any case, it is difficult to come to an agreement on the appropriate common name of a species that goes by several names in each country or region. It is even more confusing that the general name in Colombia and Venezuela for the two species of *Crocodylus* (*C. acutus* and *C. intermedius*) is "caiman," while the true caimans of the genus *Caiman* are called "babos" or "babillas" in these countries.

Lastly, I consider that with only a little more effort, it would have been possible to include the rest of the species that occur in South America (those of the southern cone: *Hydromedusa maximiliani, H. tectifera, Platemys pallidipectoris, P. macrocephala, P. radiolata, P. spixii, Mesoclemmys hogei, M. perplexa, M. tuberculata, M. nasuta, Phrynops hilarii, P. williamsi, Trachemys dorbigni*), thereby making the work truly comprehensive.

Amphibians and Reptiles of Georgia, Edited by John B. Jensen, Carlos D. Camp, Whit Gibbons, and Matt J. Elliott. 2008. University of Georgia Press (www.ugapress.uga.edu). xvii + 575 pages. Flexible cover. US $39.95. ISBN-13 978-0-8203-3111-9

JOHN J. MORIARTY
Ramsey County Parks, 2015 N. Van Dyke St.
Maplewood, Minnesota 55109 USA
e-mail: frogs@umn.edu

The Amphibians and Reptiles of Georgia has been long awaited and is much needed. Georgia as a diverse herpetofauna of 170 species and there has been no statewide treatment of its amphibians and reptiles since Martof's (1956) key and checklist.

The Introduction starts with a detailed explanation of the physiography, climate, and habitats of Georgia. The various maps showing changes in temperature and moisture from the northwest to the southeast are very helpful in explaining the variation in herp diversity across the state.

The taxonomy section is a basic primer on scientific names and Linnaean nomenclature. There is no discussion of the recent name changes in many genera and the associated publications (Frost et al. 2006; Crother 2008; Collins and Taggart 2008) are not even listed. The numerous new names for genera listed in Crother (2008) are problematic to some. I wish the authors had either provided a better explanation for or against the name changes or not included them at all. The way they are presented adds to the ongoing confusion. This will surely be a recurrent issue with other state and regional publications over the next several years as the dust settles.

The editors brought together 54 regional experts and the Georgia Herp Atlas Project to write the species accounts, which comprise the majority of the book. The accounts provide detailed descriptions of adult and larval stages. A taxonomy and nomenclature section provides useful information on relationships to other species and subspecies, although as noted above, newer scientific names are used without discussion. The distribution and habitat, reproduction and development, and habitats sections provide good information on each species. It would have been nice to have more details in these sections, but I understand that with 170 species there has to be a limit. The conservation section is nice to see for even for the

more widespread and abundant species. The county distribution maps show the most recent data collected by the Georgia Herp Atlas. In addition, the map shading shows the expected range within each county when habitat requirements are added. The color photos of the adults and larval stages with each species account are an important feature. The selection of photos, of which all but a few very rare species are of Georgia specimens, is excellent. Photos are of high quality and appropriately sized and the inclusion of images showing pattern variety and color phases provides valuable information.

The Amphibians and Reptiles of Georgia omits a dichotomous key to the species. While this is a common feature in many state works, the lack of a key is probably not a significant drawback as most general users tend to flip through the photos and do not use keys when they are provided.

The inclusion of a county map in the introduction and back inside cover is very handy for those of us not from Georgia. It would be a task to remember all 159 counties.

The references are arranged by topic and species. I find it cumbersome, but a more general reader looking for info on one species would probably find it convenient.

The listings of amphibian and reptile (frogs and alligators) calls on the University of Georgia Press website is an innovative way of accessing acoustic information. I have never used the CDs that are found in the back of some state books, but I have already visited the web to listen to the calls. My one concern is the University of Georgia Press's ability to maintain the website for years to come.

The Amphibians and Reptiles of Georgia is a tremendous resource to herpetologists and naturalists working in Georgia and throughout the southeastern United States and should be on every bookshelf. The flexible cover makes it suitable to use in the field, even though the size may limit some people from putting it in their pack.

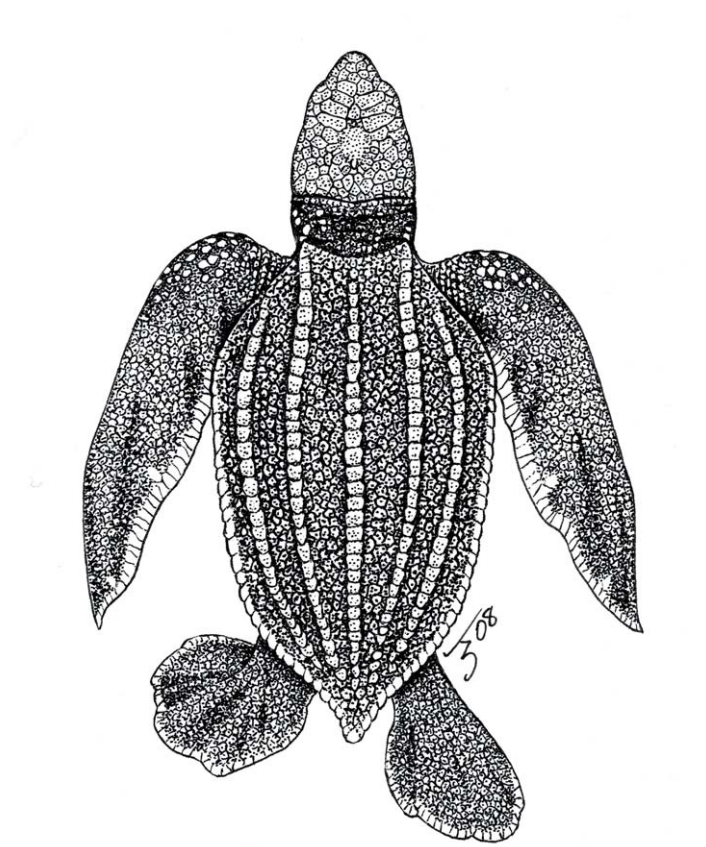
OLIVIER S. G. PAUWELS
Département des Vertébrés Récents
Institut Royal des Sciences Naturelles de Belgique
Rue Vautier 29, 1000 Brussels, Belgium
e-mail: osgpauwels@yahoo.fr

Gastronomy and herpetology being two of my main Epicurean passions, I have to confess that I was awaiting my copy of Ernie Liner's book with much impatience and salivation. One of my favorite hobbies, certainly shared with millions of people, is to look at the pictures in cookbooks. The satisfaction is often not as great as eating the illustrated dishes, but the principle is the same as visiting an art gallery. Seeing Liner's book for the first time, I examined its front cover, illustrated by a photograph of a live frog bathing in an Italian noodle soup, which I found of dubious humor, and its back cover, showing *Leiolepis* lizards being prepared, which reminded me some marvellous meals I had in northern Thailand. My disappointment was great when I opened the book and realized that these are the only photographs that the book includes.

This reasonably priced, well-bound book is printed on a good quality glossy paper, and is of a large size (8.5 x 11 inches) that is practical for culinary use, with characters big enough to be read while busy cooking. It includes a brief introduction (4 pages), followed by 952 recipes arranged in successive chapters (with 103 additional auxiliary recipes, especially for accompanying sauces and marinades), respectively on salamanders (26 recipes), frogs and toads (193), crocodiles (379), turtles (281), lizards (9), snakes (34), and recipes of indigenous people (30). The book closes after a glossary, an index, and a short biography of the author, who is a renowned specialist on the herpetofauna of Mexico. A few references to published works are made in the main text, but there is no literature cited section. 'Deep fried brandied Amphiuma,' 'Seafood stuffed frog legs,' 'Crumbed toad legs,' 'Alligator cabbage rolls,' 'Snapping Turtle in a pot,' 'Florida Green Turtle soup,' 'Cayenne Iguana stew,' and 'Baked snake with berries' are a few randomly-selected examples of the proposed recipes.

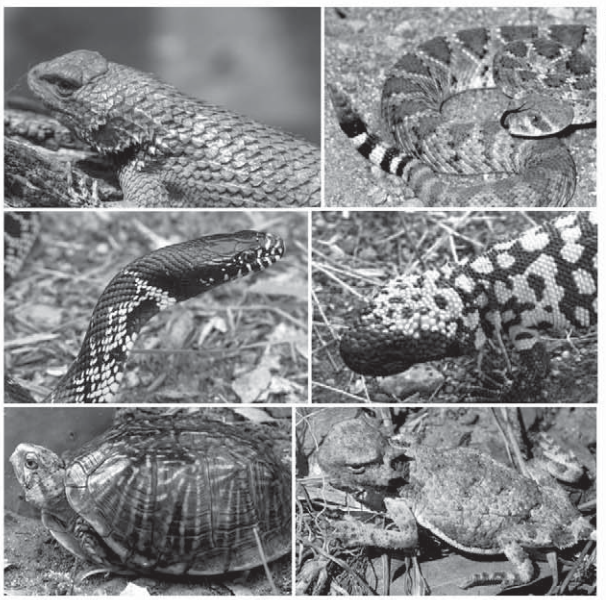
The recipes are generally short, and the ingredients are often not very specific ('frog,' 'mushroom,' 'beer,' 'white wine,' etc., without mentioning the species, the variety or the brand). This gives much space for improvisation and is actually an encouragement to apply the recipes to what ingredients are available and create personal and local versions of the recipes. The recipes are designed for a

variable number of persons, sometimes one, sometimes many more (I noted that the 'Wild game sauce piquant,' proposed for use with alligator or turtle meat, was designed for 60 persons, and that the 'Bayou Alligator sauce piquant' recipe was intended for 100+ persons). The units of measurement used and brands cited make the book practical mostly for the American public.



The publisher's note at the beginning of the book stresses the contradiction between herp conservation and the publication of a reptile and amphibian cookbook, with a hope that readers will replace the proposed herps in the various recipes with chicken. I disagree. First, many herp species are not endangered, especially those easily farmed (such as some crocodiles, softshell turtles, etc.), and their controlled consumption as food does not endanger them. Second, you do not replace a recipe's main ingredient by another without dramatically altering the result. By experience, I know for example that a ranid and a pipid do not taste the same, and that a ranid and a chicken do not taste the same at all. The recipes in the book most often do not specify which exact herp species has to be used, except in a few cases, where even highly endangered species are proposed, such as Leatherback Turtle, etc. (the Index does not list the scientific names used in the book, and only some of them are in the Glossary). It is a question of common sense and civic responsibility on the part of readers to use taxa that are currently not endangered or protected in their area, and the author is right to mention all species used in the original recipes he collected without obscuring the use of currently endangered species. In several cases the author stresses the fact that one species or another is protected.

Besides the absence of photographs, my main disappointment was that there is only rarely an indication of the geographical or cultural origin of the recipes. Gastronomy is in my opinion one way to discover other peoples' cultures, and a way to mentally travel while comfortably sitting at one's home dinner table. Even the section on indigenous people's recipes most often does not specify the country or ethnic group of origin. Moreover, I do not understand what the author meant by 'indigenous' and 'native,' and what were the criteria for putting these recipes in a distinct section. Outside this indigenous section, a series of 15 recipes are given in Spanish, i.e. the original language in which the author received them, 'to add to their historical value' says the author, but without mentioning from which country they originate! The author explains in the introduction that he gathered the recipes over decades, from various sources including anonymous ones, with no intention to be exhaustive. Whether the given recipes were born in the imaginative mind of a single person or are part of the gastronomy of a whole cultural or ethnic group is not specified. The recipes in the present book are thus a compilation of recipes the author heard of or encountered about preparing herps, with no scientific nor cultural pretention.



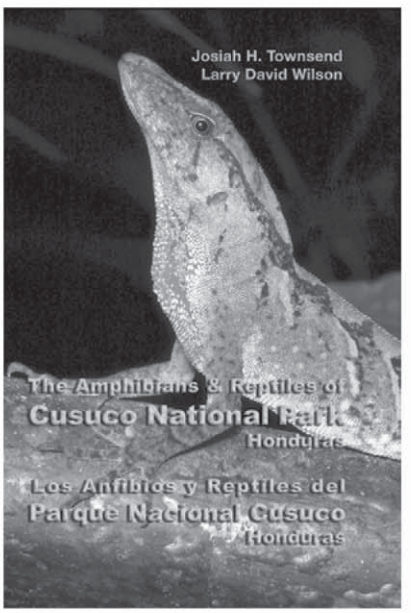
The author mentions (page 347) that 'only the larger species of lizards are of any value as food,' and the only lacertilians in the recipes he provides are *Iguana*, *Ctenosaura* and *Varanus* (there is one recipe using *Tiliqua* in the indigenous section). The back cover however shows the preparation of *Leiolepis*, a genus lizards of modest size, but there is no mention of that genus inside the book. But the author clearly specifies that there are many cookbooks and published recipes that he did not consult, especially from Asian, Australian, European, and South American sources.

Reading the text it is obvious that the author has a wide experience in herp cooking, and knows his subject very well. He provides useful tips for the best ways to cut meat and the most savory parts in turtles and crocodiles. Besides the cover photographs, the book contains a single figure (page 92), very schematic, showing Alligator meat cuts. Given the author's experience, one would have hoped to get such drawings for the other kinds of animals treated in the book, at least at the level of order.

Due to the general lack of information on the species used and the countries where they are used, the book provides a too limited an ethnoherpetological content to belong to a strictly herpetological library. It is, however, an excellent addition to any kitchen bookshelf. I recommend it not only for the numerous delicious recipes presented, but also for a number of other sakes. For instance, it should be shown to your neighbor, whose pet turtles are growing too big and who envisages releasing them in the wild. Or, it may be of special value if you live in an area where many herps are found dead on the road. Or it can help to creatively combat exotic invasive species, as the author himself suggests (the book contains nice recipes to cook *Bufo marinus*, *Rana catesbeiana*, etc.); this answers, in part, the publisher's worries regarding conservation. Many recipes, some of them very appetizing, are proposed for preparing rattlesnakes, which can in some aspects pose real safety issues. The book gives ideas for the use of alternative, cheaper, protein resources that are often neglected, even in periods of economic crisis. This book is, in general, an invitation to remind to the omnivorous species we are that there is more to eat than the few hormone-grown, warm-blooded animal species on sale at the corner supermarket.

Dermochelys coriacea (Leatherback Sea Turtle). Illustration by Jackson Shedd (www.jacksonshedd.com).

Southwestern Research



We welcome scientists and students from all parts of the U.S. and from abroad to carry out research projects. We offer comfortable cabins and a common dining room. The station also serves as a site for advanced training courses and workshops.

The SWRS Student Intern program offers students in biological sciences outstanding opportunities to observe and become involved with scientists conducting field research.

For information on research, course/workshop descriptions, the student intern program, and our bibliography of research, check out our website: http://research.amnh.org/swrs/

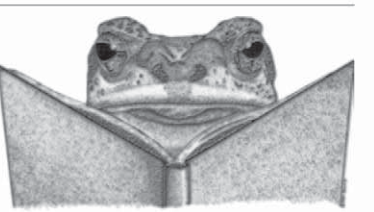
The Amphibians & Reptiles of Cusuco National Park, Honduras
Los Anfibios y Reptiles del Parque Nacional Cusuco, Honduras



Josiah H. Townsend and Larry David Wilson

Cusuco National Park in northeastern Honduras is home to 50 species of amphibians and reptiles, nine of which are endemic to the park. This book, in English and Spanish, is an in-depth guide to the park's herpetofauna.

Specifications: xiv, 322 pages, 6 x 9 inches. Hardcover (ISBN: 978-1-932871-12-8) $44.95 + postage.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

Reprints

Reprints of notes or articles published in ***HR*** may be ordered using the forms provided to authors with page proofs. Proofs are not sent to authors of Geographic Distribution or Natural History notes. Reprints may be ordered up to six months post-publication using the order form available at: <http://www.ssarherps.org/pages/HRinfo.php>

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor. Regarding missing or damaged issues, please notify *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA (tel. 785/843-1234 or e-mail: herps@allenpress.com).

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <www.ssarbooks.com>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 840		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 840	$320

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2009 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$70 (Student $35)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$95 (Student $50)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION (BASIC)** $140—includes *JH* and *HR*. **INSTITUTIONAL SUBSCRIPTION (COMPREHENSIVE)** $170—includes *JH*, *HR*, and *Catalogue*. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology,* and its newsjournal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online Allen Press website:

http://timssnet.allenpress.com/ECOMSSAR/timssnet/common/tnt_frontpage.cfm

Future Annual Meetings

2009 — Portland, Oregon, 22–27 July (with ASIH, HL)
2010 — Providence, Rhode Island, 7–12 July (with ASIH, HL)

About Our Cover: *Ceratophora tennentii*

The family Agamidae is represented in Sri Lanka by six genera, of which *Ceratophora*, *Cophotis*, and *Lyriocephalus* are endemic to the island. *Ceratophora* contains five species; collectively, these occupy three regional uplifts (massifs). The cover species, *C. tennentii*, is restricted to the Knuckles Massif, where it is a denizen of cool, montane cloud forests. These are slow-moving, diurnal lizards associated with moss and lichen-covered tree trunks. Rainfall in prime habitat ranges from 2540–5080 mm/year. The flattened, leaf-like appendage (better developed in males) distinguishes this species from congeners. Adults of both sexes attain SVLs of 60–90 mm. Gravid females have been recorded during June–August, with hatchlings observed in November and January; the latter tend to be more terrestrial than adults and are cryptic on forest floor litter. As with many species characterized by small, relictual distributions, the range of *C. tennentii* is compromised by habitat conversion for agriculture (tea and cardamom plantations) and invasion by exotic species. Given its status as a cool cloud forest species, it may face threats from warming temperatures as has been documented in another agamid, *Cophotis ceylanica*. Information for this account was obtained from de Silva et al. (2005 [2006]. Lyriocephalus 5:55–62).

The cover photo was taken by **Paul Freed**, retired Herpetology Supervisor from the Houston Zoo. Paul's career at the zoo spanned 25 years, resulting in numerous scientific and popular articles being published in national and international journals. Just prior to his retirement, Paul wrote a book, *Of Golden Toads and Serpents' Roads* (Texas A&M University Press), chronicling his world travels to observe amphibians and reptiles in the wild. Paul has relocated to the Pacific Northwest where he currently is focusing on the expansion of his herpetological photographic library.

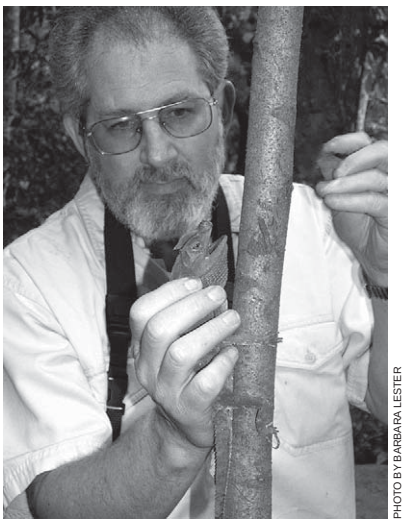

PHOTO BY BARBARA LESTER

While touring the island of Sri Lanka in March 2007 with prominent local herpetologist Anslem de Silva, Freed photographed the adult pair (male left, female right) of *Ceratophora tennentii* at Pitawala in the North Knuckles Massif. He used a Canon F-1 with a 100mm f/4 macro lens along with a Vivitar 4600 flash, recording the image on Fuji Provia 100 ISO slide film.

SSAR BUSINESS

SSAR Election Results

Results of the 2008 SSAR election are as follows:

President-Elect: .....Joseph Mendelson, III
Treasurer: .....Kirsten Nicholson
Secretary: .....Marion Preest
Board Members (Regular):
.....David Cundall, Kevin de Queiroz, Ann Paterson
Board Member (non-US):.....Patrick Gregory

All proposed amendments to the bylaws were approved. Thanks to all of the nominees who agreed to stand for positions and to Dan Noble, Elector.

—Marion Preest, SSAR Secretary

Seibert Award Winners for 2008 Announced

The 17th annual Seibert Awards were presented at the 51st Annual Meeting of the SSAR in Montréal, Québec, 23–28 July 2008. These awards are named in honor of Henri C. Seibert, an early and tireless supporter of SSAR (having served as an officer for over 20 years). In recognition of outstanding student presentations at the annual meeting, a single award was given in each of the following categories: Evolution/Systematics (5 eligible presentations), Ecology (7 eligible presentations), and Conservation (9 eligible presentations). There were no presentations in Physiology/Morphology. All awardees will receive a check for US $200 and a book from Chuck Crumly at University of California Press.

The Winners—Systematics/Evolution: **Julienne Ng**, University of Rochester, "Dewlap color and reproductive isolation in *Anolis distichus*." Ecology: **Forrest Brem**, University of Memphis, "Environmental transmission: a mechanism of disease-induced amphibian extinctions." Conservation: **David Pike**, Jonathan Webb, and Richard Shine, University of Sydney, "Landscape-scale reptile conservation: experimentally manipulating canopy cover to restore a reptile assemblage."

Honorable Mention—Ecology: **April Barreca** and Jason T. Irwin, Central Washington University, "Seasonal habitat use and movement of Cascades frogs (*Rana cascadae*) in Washington." Conservation: **Brian Todd**, Thomas Luhring, Betsie Rothermel, and Whit Gibbons, Savannah River Ecology Lab, Austin Peay State University, "Interspecific effects of upland forest clearing on amphibian migrations: implications for habitat and population connectivity."

The judges were Catherine Bevier (Colby College), Gerardo Carfagno (College of Wooster), Nirvana Filoramo (Clark University), Colleen Ingram (American Museum of Natural History), Eric Juterbock (The Ohio State University at Lima), Patrick Owen (The Ohio State University at Lima), and Emily Taylor (California Polytechnic State University).

SSAR Grants-in-Herpetology 2009 Call for Proposals

Proposals are now being accepted for the 2009 SSAR Grants-in-Herpetology Program. This program is intended to provide financial support for deserving individuals or organizations involved in herpetological research, education, or conservation. Application deadline is 28 February 2009. Grant application details are available at: http://www.ssarherps.org/pages/GIH.php.

2008 Annual Meeting, Montréal, Canada

The Annual Meeting of SSAR took place from 23–28 July, 2008 at the Le Centre Sheraton Hotel, Montréal, Canada. In addition to SSAR members, participants included members of the American Elasmobranch Society, the American Society of Ichthyologists and Herpetologists, The Herpetologists'League, Canadian Amphibian and Reptile Conservation Network, and Canadian Association of Herpetologists. The meeting was hosted by McGill University, Concordia University, Environment Canada, and Ministère des Ressources Naturelles et de la Faune. The local hosts were David Green, Andrew Hendry, Lauren Chapman, Grant Brown, David Marcogliese, Andrée Gendron, Alain Branchaud, Jacques Jutras, Heather Gray, Ronald Javitch, and Ray Saumure. The hard work of the local hosts, the staff of the Kansas State University Division of Continuing Education (especially Heide Burke and Sharon Brookshire), and over 30 volunteers ensured that we had another smooth-running meeting.

Numbers were down somewhat at this year's meeting. There were 862 herpetologists and ichthyologists from 22 countries (including Australia, Belize, Brazil, France, Japan, Norway, Poland, and Taiwan) and 15 exhibitors. Approximately 45% of attendees were students and around 480 papers and 250 posters were presented. Close to 40% of the papers and posters were herpetological. Two graduate student workshops and six symposia were held. One symposium was sponsored by SSAR: "Is Management of Sustainable Commercial Harvest of Long-Lived Organisms Possible?" Willem Roosenburg, Justin Congdon, Henry Mushinsky, and Rich Seigel were the co-organizers and SSAR thanks them for their efforts. The Henri Seibert Competition attracted 21 students in three categories this year.

Joe Mendelson, III (left) and Greg Watkins-Colwell (right) enjoying a break between paper sessions. Photo by M. Preest.

Participants in the SSAR-sponsored symposium "Is Management of Sustainable Commercial Harvest of Long-Lived Organisms Possible?" Top row (L to R): Willem Roosenburg, Ron Brooks, Justin Congdon, Jack Musick, Rich Seigel, Wade Smith, Earl McCoy; Bottom row (L to R): Tony Gamble, Paul Moler, Henry Mushinsky. Photo by M. Preest.

Most participants were in the Conservation category.

The Annual Meeting began officially at 0830 h on Thursday, July 24th with warm welcomes from David Green (chair of the Local Host Committee) and Rachel Leger (Directrice, Biodôme de Montréal). Joseph Mendelson, III from Zoo Atlanta then spoke about "Research, Conservation, and the 2008 Year of the Frog Campaign." Joe presented some truly alarming statistics relating to amphibian declines and extinctions that will be familiar to many SSAR members. He indicated that research as usual and conservation as usual are not a sufficient response to the crisis and that innovative, cross-disciplinary research is needed. Some of this research is outlined in the Amphibian Conservation Action Plan (http://www.amphibianark.org/pdf/ACAP.pdf).

Pat Gregory then presented David Green with the 2008 Distinguished Herpetologist Award from the Canadian Association of Herpetologists. Stevan Arnold was the recipient of the 2008 Fitch Award for Excellence in

This year's President's Travelogue was presented by Board Member Jimmy McGuire. Photo by M. Preest.

Attendees at the SSAR Student Reception held on July 24th listening to President McDiarmid welcoming them to the meeting. Photo by M. Preest.

Herpetology and Al Savitzky was presented with a plaque for receiving the Robert K. Johnson Award in 2007. Rick Mayden gave the ASIH plenary address on "A New Paradigm on Biological Species: the Nexus of Theory and Operationalism Essential to Biodiversity Studies." Pat Gregory, the 2008 Herpetologists' League's Distinguished Herpetologist, spoke about "Northern Lights and Seasonal Sex: Reproductive Ecology of Cool-Climate Viviparous Snakes." Kenneth Goldman then made a presentation on the past, present, and future of the American Elasmobranch Society.

Social Events

Jimmy McGuire (Museum of Vertebrate Zoology, UC Berkeley) was a good choice for the President's Travelogue and this event (on July 24th) was attended by around 60 people. These presentations are always a treat and this year was no exception! Jimmy spoke on "Herpetological Diversity and Biogeography of Sulawesi, Indonesia—the World's Coolest K-Shaped Island."

The Joint Meeting Reception was held the next evening in the Biodôme de Montréal (formerly an Olympic velodome). Inside was a journey through five ecosystems; tropical rainforest, Laurentian forest, the St Lawrence marine, Arctic, and Antarctic.

This year SSAR offered two special social events for our student members. We hosted a very successful Student Reception on the evening of July 24th and invited all attending students and a number of professional herpetologists. This was intended as an opportunity for the students to meet professionals in their field, to make useful contacts, and to encourage their participation and contributions. A variety of items provided by Kraig Adler and Dawn Wilson were offered as door prizes.

We also held a Pizza Lunch offsite on July 25th for students particularly interested in becoming more involved

in the Society. We talked about various ways of increasing their involvement and generated a number of interesting ideas to raise funds to support student attendance at the Annual Meeting.

Following the group photograph, the Joint Meeting Picnic had to be held indoors. For the past five years, three of our picnics (Norman, Tampa, and now Montréal) have been driven indoors because of inclement weather. We were however rewarded with lively traditional Québécois music and dance by Les Bons Diables. Most then took advantage of the close proximity of the Redpath Museum and spent some time wandering through the exhibits. There was also a live collection of local amphibians and reptiles.

The SSAR/HL Live Auction occurred on July 27th and, although the turnout seemed low, we raised an impressive $5,200. Several hard-working and dedicated graduate students (including Mallory Eckstut, Rocky Parker, Alison Hamilton, and Devin Bloom) resurrected the Silent Auction at the last minute (literally a week before the meeting began). This was a joint SSAR/ASIH effort and it raised over $2000 for graduate student support.

The Joint Meeting Banquet was held on the last evening of the meeting, and Pat Gregory served as Master of Ceremonies. Pat acknowledged Past-Presidents of the participating Societies. Three of SSAR's Past-Presidents attended the Banquet (Al Savitzky, David Green, and Darrel Frost) and there were certainly others at the meeting this year. HL and ASIH made various awards and ASIH announced the results of their recent election. Carl Ferraris issued an invitation to attend the 2009 Joint Meeting of Ichthyologists and Herpetologists in Portland, Oregon, 22–27 July).

Board Meeting and Business Meeting Summaries

Society President Roy McDiarmid called the board meeting to order at 0803 h on July 23rd, 2008 in the Le Centre Sheraton Hotel, Montréal, Canada. In attendance were eight members of the Board of Directors and 12 editors, committee chairs, or members of the society. Minutes of the 2007 Board of Directors Meeting (St. Louis) were approved.

Annual reports for 2007/2008 were submitted by all officers, editors, and committee chairs. President McDiarmid reported devoting much time since the 2007 meeting to dealing with various issues raised in St. Louis. For example, he has been involved in discussions with Henry Mushinsky (SSAR representative on the Joint Meeting Committee [JMC] and incoming ASIH President) and Brian Crother (SSAR President-Elect) on the functioning of the JMC, the perceived dominant role of ASIH in that activity, and the role of SSAR and other societies (e.g., HL, AES). Additionally, he has been working on initiatives designed to respond to concerns expressed by several student members at the annual business meeting and at other social venues in St. Louis that many did not feel that they were an integral part of the society and did not always have a positive and welcoming experience at our meetings. Following receipt of a letter of resignation from Geoff Smith (Editor, *Journal of Herpetology*), Brian Crother and Roy reviewed the duties and current structure of the editorial office. As a result of this review and subsequent discussions with Geoff Smith and a former editor (Brian Sullivan), they identified and interviewed a candidate for the position; he is Matt Parris, University of Memphis, and is currently an associate editor of the journal. Roy appointed Raul Diaz as new web czar and arranged for Catherine Bevier and Alan Savitzky to represent SSAR at an AAAS/AIBS NSF funded Education Summit and for Jimmy McGuire to present the President's Travelogue at the 2008 Annual Meeting.

Treasurer Kirsten Nicholson reported that the society's expenses were well within the approved budget limits, but they exceeded revenues by $15,403. This was due in large part to a significant shortfall in membership income. The shortfall may be offset ultimately by an increase in membership (new and renewing) early in 2008. The society's Membership Office is currently being managed by Allen Marketing and Management (AM&M), which assumed responsibility in May 2007. The transition to AM&M's handling of membership has been somewhat rocky. However, overall, Kirsten is pleased with the service provided. This service is not inexpensive and Cecelia Widdison (in the Publication Secretary's office) has indicated that she is interested in resuming membership duties and could do so at a substantially lower cost. The board decided to ask Cecelia for a formal proposal and will reconsider this matter at the 2009 board meeting.

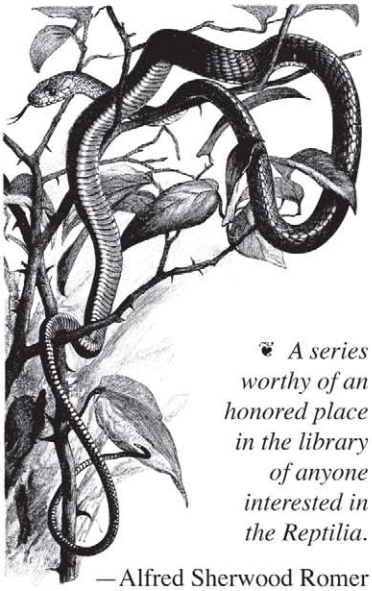
The society's investments performed well and the entire portfolio increased by $46,390 with nearly $3,000 in realized investment income. The society's investment objective is to maximize return on investment while preserving the original principal amount of all restricted funds. Towards this end, the portfolio was rebalanced in March 2006, and has been performing well. Income shortfalls necessitated cashing in $40,000 from our investments to pay society bills. For easier financial management, Kirsten plans to consolidate several bank accounts into an account established by Allen Press. Most of the President's Fund was used to support SSAR's 50th Anniversary celebration last year. Kirsten presented summaries of the Book Initiatives and Student Awards Funds. The Roger Conant library, which was picked up in Albuquerque several years ago and is now in Salt Lake City, will be auctioned in the near future.

In the past year, Secretary Marion Preest prepared board and business meeting agendas and minutes for officers, editors, and committee chairs. Additionally, she prepared a summary of the 2007 meeting for publication in *Herpetological Review* and prepared the Annual Report for this year's board meeting. Ongoing duties include updating SSAR letterhead and material on the website, answering or forwarding numerous emails, and ensuring that reports from committee chairs are submitted for publication. Marion was involved in the student activities planned for the Montréal meeting, Nominations Committee duties, and she headed an effort to increase email contact with members. She made copies of photographs taken at the 50th Anniversary celebration in 2007 available for purchase at the Annual Meeting (Raul Diaz is working on making photographs available via the website). She has also been working on compiling a list of international herpetological societies so that SSAR can acknowledge significant events (e.g., anniversaries) as they occur in our sister societies.

Breck Bartholomew (Publications Secretary) reported that total income from the Publications Office in 2007 was $93,720. This included $49,564 in membership dues collected before AM&M assumed membership duties.

Andy Price (Editor, *Catalogue of American Amphibians and Reptiles*) reported that 20 accounts were published in 2007. He is revising the *CAAR* "Instructions for Authors." He brought two issues to the board's attention.

(1) For a variety of reasons the *CAAR* Board of Editors has been unable to maintain an annual publication schedule of 20 accounts. Andy therefore recommended that *CAAR* adopt an 'as ready' publication schedule; that is, when 20 accounts are ready they are published regardless of the time frame involved. Subscribers will then renew for the next issue of 20 accounts.



(2) Andy plans to ask the *CAAR* Board of Editors to begin soliciting authors to prepare revisions of existing accounts. He believes this step will be of benefit to the *Catalogue* for reasons including changes in taxonomy, significant changes in geographical ranges, substantial increases in the body of literature pertaining to given taxa, and our ability to publish color illustrations.

There was discussion of the implications of an "as ready" publication schedule for SSAR members who receive copies of *CAAR* as part of their membership (e.g., Plenary members, *CAAR*-only members). A suggestion was made that *CAAR* not be included in certain membership categories, but that individuals indicate when they renew if they wish to receive *CAAR* (which they would then be billed for). Plenary memberships would no longer be available.

The board approved Andy's suggestion that he ask authors to prepare revisions of existing accounts. The board was clear that it is the editor's prerogative to replace section editors should they not be performing adequately.

Kraig Adler (Editor, *Contributions to Herpetology*) reported that a number of books in this series were published recently. *Contributions to the History of Herpetology*, Volume 2 was distributed *gratis* to the del-

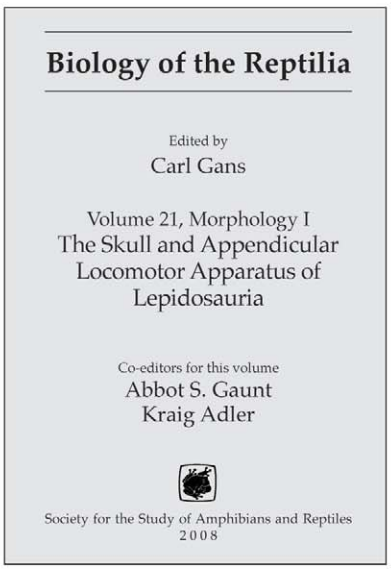
The Two Final Text Volumes in This Series from the Society for the Study of Amphibians and Reptiles

❦ *A series worthy of an honored place in the library of anyone interested in the Reptilia.*

—Alfred Sherwood Romer (*American Scientist*)

❦ *A broad, unified treatment of everything concerning the structure and the life of living reptiles.*

—Benedetto Lanza (*Scientia*)



❦ *There has been no work comparable to this in any language.*

—Garth Underwood (*British Journal of Herpetology*)

BIOLOGY OF THE REPTILIA

THIS CELEBRATED SERIES, NOW EXTENDING TO 21 VOLUMES, HAS BEEN WIDELY acclaimed as the definitive resource on reptilian biology. From the first volume in 1969, the distinguished contributors to this series have included an international group of more than 100 experts in their respective fields. Each volume consists of multiple chapters summarizing the state of our knowledge, laying groundwork for future research, and providing an in-depth guide to the relevant literature. All volumes are fully illustrated with figures, graphs, and extensive tables of information. Each volume has both subject/species and author indices. A comprehensive and cross-referenced index to the entire series, to be published as the final volume, is in preparation. SSAR has been proud to assume responsibility for this classic series and to offer clothbound volumes at affordable prices.

General Editor: Carl Gans
Co-editors of Previous Volumes:
***Morphology* (seven volumes):** Angus d'A. Bellairs, Abbot S. Gaunt, Thomas S. Parsons
***Physiology* (five volumes):** David Crews, William R. Dawson, K. A. Gans, F. Harvey Pough
***Ecology and Behavior* (two volumes):** Raymond B. Huey, Donald W. Tinkle
***Neurology* (three volumes):** R. Glenn Northcutt, Philip S. Ulinsky
***Development* (two volumes):** Frank Billett, Paul F. A. Maderson

• VOLUMES 20 AND 21: TO BE PUBLISHED AS A SET (DECEMBER 2008) •

Morphology, Volumes H and I: Edited by Carl Gans, Abbot S. Gaunt, and Kraig Adler

Topics and authors: *The Skull of Lizards and Tuatara,* by Susan E. Evans; *The Snake Skull,* by David Cundall and Frances Irish; *The Appendicular Locomotor Apparatus of* Sphenodon *and Normal-limbed Squamates,* by Anthony P. Russell and Aaron M. Bauer; *The Skull of Serpentes,* by Samuel B. McDowell; *An Atlas of Amphisbaenian Skull Anatomy,* by Carl Gans and Ricardo Montero.

These well-illustrated volumes summarize the skulls and appendicular skeletons of lizards, snakes, tuatara, and amphisbaenians. As such, they will be of interest to zoologists and herpetologists but also to veterinarians and herpetoculturists. Each chapter includes descriptive morphology combined with discussions of function and of ecological and evolutionary relationships. These are the final text volumes.

Specifications: *Volume 20*: 770 pages, 214 figures, indices (ISBN 978–0–916984–76–2); *Volume 21*: 792 pages, 151 figures, indices (ISBN 978–0–916984–77–9). Both volumes will be clothbound with dust jackets. To be published 1 December 2008.

***Price per set of two volumes*:**	***Shipping cost per set*:**
SSAR members *before 31 March 2009* . . . . US$120	Shipping will be charged at cost.
Institutions and Non-members . . . . . US$140	Insurance is extra, on request.

Send orders to: Breck Bartholomew, SSAR Publications Secretary, P. O. Box 58517, Salt Lake City, Utah 84158–0517, USA (*telephone*: area code 801, 562–2660; *e-mail*: ssar@herplit.com). Make checks payable to "SSAR." Overseas customers may make payment in USA funds using a draft drawn on American banks or by International Money Order. All persons may charge to MasterCard, American Express, Discover Card, or VISA (please provide account number and expiration date). SSAR membership details and a complete list of all Society publications can be obtained on request to the Publications Secretary (address above). For details, check the Society's webside at www.ssarherps.org.

NOTE: Copies of Volume 19 (Morphology G, 660 p.) are available at $58.00. SSAR did not publish and does not sell volumes 1–18 in the series.

egates at the St. Louis meeting. *Tasks and Problems in Studying the Life of Reptiles in Zoos*, by Hans-Günter Petzold was published in May 2008 and *Biology of the Reptilia*, Volumes 20–21 are expected in September, 2008. A number of books are planned beyond 2008, including *Biology of the Reptilia*, Volume 22 (a cumulative index of the series).

Editor of *Facsimile Reprints in Herpetology*, Aaron Bauer, reported that a softcover version of *The Life and Herpetological Contributions of August Friedrich Schweigger* is being printed in Manaus, Brazil, and the book will be given to all attendees of the 6th World Congress of Herpetology (WCH) thanks to a donation from Ronald Javitch. This will be coupled with a membership drive at the meeting (the new membership brochures will be available). A hardcover edition will be printed by September, 2008. Publication of *Gray's Catalogues of the Specimens of Amphibians and Reptiles in the Collection of the British Museum* was postponed due to the need to complete the Schweigger volume for the WCH. Other works are in various stages of completion.

Herpetological Circulars Volume 37 was printed in January, and John Moriarty (Editor) indicated that Volume 38 would be printed by the Annual Meeting. The use of print-on-demand for recent *Circulars* keeps the original printing costs and inventory to a minimum, but requires the reprinting of better selling *Circulars*. This printing technique allows for short run reprints at reasonable prices. There previously was no budget item to allow for the reprints. John would like to start budgeting for anticipated reprints.

The Editors of *Herpetological Conservation* (Joe Mitchell and Robin Jung Brown) reported that Volume 3 (*Urban Herpetology*, edited by J. C. Mitchell and R. E. Jung Brown) is nearing completion and is scheduled for publication in Fall, 2008. Joe will continue as editor for one more volume, but Robin is stepping down. Meredith Mahoney suggested that Joe might consider publishing the proceedings of an upcoming SSAR-sponsored symposium ("Headstarting Turtles—Learning from Experience").

Robert Hansen (Editor) reported that *Herpetological Review*, Volume 38 was slightly smaller than Volume 37 and that submission rates appear to have leveled off. There were several staff changes during 2007. Managing Editor Tom Tyning ended his long-running tenure with *Herpetological Review* at the end of 2007. Meredith Mahoney (Illinois State Museum) became an Associate Editor in late 2007, Michael Burger concluded his stint as Section Editor for Herpetological Husbandry and was replaced by Brad Lock (Zoo Atlanta), thus ending the Dallas Zoo's multi-decade long staffing of this position. Michele Johnson (Section Editor, Current Research) resigned and was replaced by Ben Lowe (San Diego State University). A new section, Amphibian Chytridiomycosis Geographic Distribution, appeared in the final issue of 2007. The board continued its ongoing discussion of making *Herpetological Review* available online and voted unanimously to support this change. Effects on membership will need to be considered. Roy will ask Bob to pursue this and contact BioOne to discuss the possibility and implications of this change.

Geoff Smith, Editor of *Journal of Herpetology*, submitted his letter of resignation and reported a number of staff changes in the past year (two new Associate Editors). He supports appointing Matt Parris as his replacement. Submission rates for *Journal of Herpetology* continue to increase and the rejection rate remains stable at around 60%. The 2007 budget was overspent by approximately $11,500 due to an increase in the average length of papers published and this increase in manuscript size continues in 2008. To deal with this, Geoff has reduced the number of papers that will appear in the September and December issues.

Journal of Herpetology will continue with its use of color images on the front cover. The paper used for printing the journal for several years was recently officially certified by the Forest Stewardship Council. Geoff plans to work with his replacement to revise the current "Guidelines for Authors" on the website. Geoff is recommending that the table of contents revert from its subject category arrangement to the original undivided layout and that all papers and notes be published with author-generated keywords that would be searchable and used by an indexing service. The majority of the board voted to do away with categories and suggested using symbols that would appear on the legend on the back cover to show the cross-categorization of papers.

Joe Mendelson, III expressed some concern that the *Journal* might be losing potential authors because of the slow turn around time for submissions. The problem appears to be due to delinquent reviewers. The editor needs to remind reviewers of how important timely reviews are. It might be necessary to increase the number of reviewers to whom each paper is sent and then accept the reviews of the first two or three that are received.

Matt Parris was introduced by Roy and then talked about his experience with *Journal of Herpetology* and what his philosophy as an editor would be. Matt was asked what support he would receive from his home institution (University of Memphis). He indicated that he will receive release from service responsibilities and access to an assistant funded out of a budget for teaching assistants. Matt was excused from the room, and, following brief discussion, the Board voted unanimously to approve Matt's appointment as Editor of *Journal of Herpetology*.

The 50th Anniversary Celebration Committee was composed of Bob Aldridge, Janalee Caldwell, Jonathan Losos, Henry Mushinsky, Kirsten Nicholson, and Al Savitzky (Chair), with Robin Andrews and Roy McDiarmid serving as *ex officio* members. The 50th Anniversary celebration was held during calendar year 2007, with primary emphasis on events at the annual meeting in St. Louis. The committee acknowledges with gratitude the support and assistance of many individuals, particularly Roy McDiarmid and Kraig Adler for their tireless efforts to ensure that this important milestone in society history was celebrated in a manner befitting the magnitude of the occasion. Major items extending throughout the year included the production of special covers for the *Journal of Herpetology*, a special banner on the cover of *Herpetological Review*, a highly successful celebratory banquet at the St. Louis meeting with elegant commemorative wine glasses etched by Ronn Altig with a modified society logo of his own design provided to all banquet attendees, and a special edition of the SSAR Auction with Joe Collins reprising his role as auctioneer. SSAR provided several items *gratis* to all meeting participants. These included *Contributions to the History of Herpetology, Vol. 2* by Kraig Adler, John S. Applegarth, and Ronald Altig (supported by a generous gift from Ron Javitch), a beautiful photographic poster by Dave Dennis (with production assistance from Breck Bartholomew), and a history of the society by John Moriarty and Breck Bartholomew.

Over the past year, the Conservation Committee (Stephen Richter and Betsie Rothermel, co-chairs) worked toward a long term goal of collaborating more with other professional committees (e.g., ASIH Conservation Committee) and with conservation organizations (e.g., Partners in Amphibian and Reptile Conservation, PARC). The committee was asked to lend its support to a planned symposium on the effects of roads on herpetofauna, to be held at the 2009 Joint Meeting in Portland. The Conservation Committee agreed that this was an important issue and so has joined with ASIH and other organizations in endorsing and promoting this event. In February 2008, committee member John Jensen played an active role as an organizer and moderator for the Southeast PARC meeting held in Athens, Georgia. He reported that the meeting was well attended and addressed many pressing concerns of interest to members of both SSAR and PARC, including emerging diseases, land acquisition and protection, and outreach and education. Stephen Richter intends to phase out of his role as co-chair of the committee this year and Betsie Rothermel and Joe Mendelson, III will serve as co-chairs.

Seven proposals of high quality were submitted for the Dean Metter Award this year (Joe Beatty, Committee Chair). The committee requested permission from President McDiarmid to make two awards this year and that request was granted. The first awardee is Emilie Throop of Kansas State University. She is working on a Masters degree under the direction of Kimberly With in the Division of Biology and wrote an outstanding proposal entitled "Habitat Suitability and Metapopulation Dynamics of a Native Tallgrass Prairie Reptile." The other equally impressive proposal was put together by Fernanda Werneck who is working on her Ph.D. under the supervision of Jack Sites in the Department of Integrative Biology

at Brigham Young University. Her proposal deals with South American lizards (two gekkonids and a gymnophthalmid) and is entitled "Phylogeography and Conservation of Lizards from Seasonally Dry Tropical Forests of South America."

Erik Wild and Josh Kapfer (co-Chairs, Grants-in-Herpetology Committee) reported that 62 proposals from 23 US states and eight countries (including the United States) were received in 2008. The "Laboratory" category received the most applications (16). The following winners will each receive $500:

Conservation: Sara M. Maxwell, University of California Santa Cruz
Field Research: Sarah Becker, Southern Illinois University
Laboratory Research: William T. McLamb, Florida Institute of Technology
Travel: Kyna M. Hogg, University of North Dakota
International: Michael Hailu, Addis Ababa University, Ethiopia
Education: Mike Hickel, Rolling Hills Wildlife Adventure, Salina, Kansas

Co-Chairs of the Henri Seibert Award, Lora Smith and Margaret Gunzberger announced the winners of the 16th annual Seibert Award at the meeting in St. Louis, 2007 (published in *Herpetological Review* 38:380). SSAR wishes to thank Chuck Crumly (UC Press) for once again providing books for the winners. There was some discussion of whether a student could enter another Seibert category after they have won previously, e.g. if they have won the Conservation category can they enter the Morphology/Physiology category. The board decided that strict interpretation of the guidelines would not permit this. Pat Owen has replaced Lora and Margaret as chair of this committee.

Cathy Bevier (Chair, Herpetological Education Committee, HEC) reported that members of this committee continue activities that are in line with their mission, including fielding questions from community members and students about herps and conducting outreach programs to local groups and schools. These informal educational pursuits are noteworthy, but expanding the reach of the HEC to a greater section of the public could happen with a more extensive web page that is linked with the herpetology society web pages. This will be a major project over the next year, and information will potentially include teaching modules, curriculum suggestions, and links with websites from different states that contain information on amphibian and reptile species diversity. Several potential initiatives that HEC can pursue have grown from Cathy's attendance at a recent meeting, "NSF Conversation in Undergraduate Biology – AAAS/AIBS Biology Education Summit." Part of the meeting focused on identifying the needs of resources and knowledge for successful biology students in the 21st century.

The board discussed various projects the HEC could consider to raise the profile of herpetologists, e.g., creating a "How to Become a Herpetologist" webpage, including herpetology-related laboratory teaching modules on the webpage, posting herpetology data sets that could be used by classes for analysis, making back issues of *Journal of Herpetology* and *Herpetological Review* available either free or deeply discounted to students in Herpetology or Vertebrate Biology classes as a recruitment tool. Cathy will talk with Breck Bartholomew about the possibility of this last suggestion.

Lynnette Sievert (Chair, Kennedy Award Committee) announced that the winning paper for 2007 is by Guohua Yu, Junxing Yang, Mingwang Zhang, and Dingqi Rao: "Phylogenetic and Systematic Study of the Genus *Bombina* (Amphibia:Anura: Bombinatoridae): New Insights from Molecular Data," *Journal of Herpetology* 41:365–377. Guohua will receive a check for US $200 or $400 in SSAR publications.

Henry Mushinsky reported that he was resigning from his role as representative for SSAR and HL on the Meeting Management Committee (MMGC). He suggested that each society should elect or select an individual to represent their society on this committee. He intends to serve on the committee for one more year as a representative of ASIH. During April, members of the MMGC and the Meeting Planning Committee met in Montréal and spent three days reviewing the conference facilities and developing the overall schedule including business meetings, workshops, social events, and poster and oral presentations. The deadline for abstract submission was extended for the 2008 meeting because the meeting was undersubscribed at the original deadline. Henry provided a reminder that each person can only submit one oral paper and one poster for presentation at the annual meeting. The MMGC feels that their efforts to better coordinate and organize symposia have been well-received and worthwhile. Symposia organizers have formatted their symposia to fit within a predetermined schedule and have been responsive to requests to be sure all participants are properly registered and have submitted their abstracts in a timely manner.

Meetings are planned for Portland in 2009 and Providence in 2010. The MMGC is aware that a World Congress of Herpetology has been proposed for Vancouver, British Columbia, Canada for 2012. Henry suggested that every effort should be made to integrate the four JMIH sponsoring societies into the WCH meeting plans.

Kirsten Nicholson (Chair, Nominations Committee) reported that no elections were held in 2007. In 2008, the society needs to elect a president-elect, three regular board members, and one non-US board member. Kirsten Nicholson and Marion Preest are willing to run again for the positions of treasurer and secretary, respectively. For the first time, voting will be carried out electronically. AM&M will post the list of candidates and their biographical sketches online, then will email the membership and provide instructions on how to login and vote. An Election Officer (Dan Noble, University of Guelph) has been appointed.

In the context of discussion about society resolutions, a suggestion was made that, annually, the president writes personal letters acknowledging those who have served the Society in the previous year (e.g., editors, committee chairs and members, etc). Those who have provided the society with special service could additionally be acknowledged with a brief paragraph and photograph in *Herpetological Review*. Brian Crother and Kraig Adler agreed to work on this with help from Marion Preest.

The 6th edition of the Standard English and Scientific Names List has been published. Brian Crother (Chair) is working with Anne Maglia and Raul Diaz to put an edited 6th edition on the web. This will not be a simple static pdf of the hard copy, but a changeable document for easy updating. The 6th edition has attracted attention because of certain name usage and there are two items that Brian brought to the board's attention. One is the authority of the list. This list is called the "Official Names List" for SSAR, ASIH, and HL. This means that these are the *standard English names* to be used, at least for SSAR journals. This rule is simply meant to differentiate among competing English names lists. As for scientific names, these are hypotheses and in no way does this list dictate the use of scientific names published in SSAR journals or any other journals. The second item discussed related to the review of this list prior to publication. The publication editor, John Moriarty, sends the entire document out for review prior to publication. These reviews have always yielded a number of issues to which the committee has had to respond. Brian wondered whether the list should undergo a more expansive review process. The board did not think this was necessary. A suggestion was made that a description of the review process could be included on the cover of the issue in which the list is published.

At the board meeting in St. Louis, Dawn Wilson resigned as chair of the Silent Auction Committee (a service she has provided for many years). This committee raises funds for student travel. Dawn suggested that SSAR come up with other ways to raise funds. She was subsequently appointed as chair of the new Student Participation Committee. There was discussion of increasing the size and/or number of Travel Awards given each year. The board voted unanimously to double the size of the budget for these awards, i.e., ten awards of US $400 each will be given out in 2009. Dawn reported that the number of applicants for Travel Awards continues to be low (16 applications for 10 awards in 2007).

Anne Maglia (Chair, Web Oversight Committee) thanked Zack Walker for his valuable service as webmaster for several years and announced

that he has been replaced by Raul Diaz. Among other changes, Raul has added the SSAR logo to the URL address bar, updated contact information, text, and available PDFs, fixed links on the History of Herpetology page and PDFs that open within the browser page, added an SSAR PUBLICATIONS link on the drop menu under "PUBLICATIONS" for a link to the publications available through HerpLit, updated the annual meetings section as well as other society's conferences, and increased monthly bandwidth by 33%.

Al Savitzky (SSAR Representative to AIBS and BioOne) reported that he attended the annual BioOne Publishers and Partners meeting in April and the annual meeting and associated activities of the AIBS in May, 2008. AIBS continues to serve its member societies in two major areas, public policy and education. Both of these offices were again consumed during the year with issues surrounding the teaching of evolution. Anti-evolution bills appeared in several state legislatures under the new guise of "academic freedom" bills, with the tag line "teach the controversy." Such bills are simply an attempt to re-introduce "intelligent design" curricula where they have previously been defeated or ruled unconstitutional. The Public Policy Office and elected officers of AIBS were active in providing authoritative arguments for their defeat. Other public policy activity by AIBS was directed toward monitoring and supporting the funding of biological research by NSF, which continues to lag far behind support for NIH under the present administration.

Two members of the AIBS Public Policy Office, Holly Menninger and Robert Gropp, published a booklet in 2008 entitled *Communicating Science: A Primer for Working with the Media*, which is available from the AIBS. As usual, the annual meeting of AIBS centered around a single major theme. This year's meeting was devoted to Climate Change and Human Health and featured internationally prominent speakers. The AIBS meetings were followed by an Education Summit, which consisted primarily of presentations on a range of subjects, e.g., threats to the teaching of evolution, increasing the involvement of under-represented groups, the future of textbook publishing in biology. A representative of McGraw-Hill said that he is informing his authors that they should plan on having only one or two more editions published in print, before textbooks become exclusively electronic. Another important element of the Summit was discussion of the pros and cons of establishing national standards for undergraduate programs in biology.

BioOne held its annual one-day meeting of representatives from publishers (primarily professional societies), academic libraries, and a few commercial presses. The program included updates on BioOne activities and presentations on several related topics. The major development in the coming year will be the migration of BioOne to a new platform. In addition to giving BioOne itself a new look, the new platform will provide important advantages for publishers (societies), libraries, and users.

Catherine Norton, Deputy Director of the Biodiversity Heritage Library (www.biodiversitylibrary.org), provided a detailed update on that project, which is an element of the broader Encyclopedia of Life that was launched in May, 2007 with major funding from foundations and several large biodiversity institutions. The goal of the BHL is to produce an open-access digital library of the biodiversity literature, which includes about 5.4 million books dating back to 1469, as well as 800,000 monographs, and 40,000 journal titles (12,500 of them current).

Al Savitzky suggested that SSAR consider approaching the Biodiversity Heritage Library about scanning back issues of *Herpetological Review*. Alternatively, or in addition, SSAR might consider the benefits of publishing *Herpetological Review* through BioOne. Al will work with Bob Hansen to investigate this. A concern was expressed regarding the color photos and complicated formatting of *Herpetological Review* and the searchability of the material in the publication.

During the discussion period, a question arose regarding the transition from print to online-only publication. The answer from a staff member of BioOne was that such a transition was indeed still coming, and sooner than we expect. The impact of online-only publication on the size of society memberships is now a matter of immediate concern and should be the subject of pro-active planning.

Richard Durtsche (Symposium Coordinator) did not receive any symposium proposals by the February 1 deadline. Dick reported being contacted by HL regarding co-sponsorship as they had received three proposals (two requesting funding). In working with the HL symposium committee chair, Rafael de Sá, it was agreed that the societies (SSAR and HL) would co-sponsor both symposia requesting funding. The first symposium, with lead sponsorship by HL, is entitled "Reproductive Biology of the Ophidia." The second symposium, with lead sponsorship by SSAR, is entitled "Headstarting Turtles—Learning from Experience." The second symposium was later withdrawn, although plans are to resubmit a proposal next year.

This concluded discussion of reports submitted, and the board then turned to new business. The Zoo Liaisons Committee has been defunct for a number of years. It was originally intended to try to bridge the gulf in herpetology between the "zoo people" and those in academia. Joe Mendelson, III led a discussion of this committee and suggested that this gulf does not exist to the degree it did years ago and that herpetologists in the zoo community typically do not attend meetings like the JMIH, not because they don't feel welcome, but, rather, because they have their own meetings. Joe offered to spearhead a membership drive among the zoo community. He suggested, and the board approved, that student membership rates be made available to zoo keepers. The board voted unanimously to abolish the Zoo Liaisons Committee.

This year the society ran out of an issue of *Journal of Herpetology* and had to print an expensive rerun. Partly this was due to interpreting Article VII, Section 3 from our bylaws (see below) such that individuals who failed to renew their memberships would still receive copies of our journals in March and June of the year in which they were delinquent.

Article VII. Dues

Section 3. A member in arrears for payment of dues for a period of 6 months after conclusion of the current membership year shall be dropped from the role after due notice from the Secretary.

The board voted to ask the membership to approve rewording Article VII, Section 3 of the bylaws (as below) so as to avoid this problem in the future. This will be included in the 2008 ballot.

"A member in arrears for payment of dues for a period of 2 months after conclusion of the current membership year shall be dropped from the role after due notice."

Earlier in 2008, Roy and Brian approved a request for $1000 towards publication of a book titled "Lizards of the American Southwest: A Photographic Field Guide." In this agreement they arranged for SSAR to get four *gratis* copies and the opportunity to buy copies of the book at $13 (45% of retail). Roy and Brian agreed to look at a draft of the book, as well as other works produced by the publisher, and decide whether it is appropriate for the SSAR logo to appear on the book. Decisions like this could be made at the level of the board rather than solely by the president.

There is some inconsistency in the membership dues listed in various places, e.g., on the website, in *Journal of Herpetology*, in the new membership brochure, etc. In order to prevent this from occurring in the future, membership pricing will only be included on the website and any changes to the dues structure will be made there. Following a consideration of past dues increases and comparison with dues for ASIH and HL, the board voted unanimously to increase individual dues by 15% (rounded up) and institutional dues by 20% (rounded up). Thus, a regular membership will increase from $60 to $70 and a student membership will increase from $30 to $35. This change will take effect immediately.

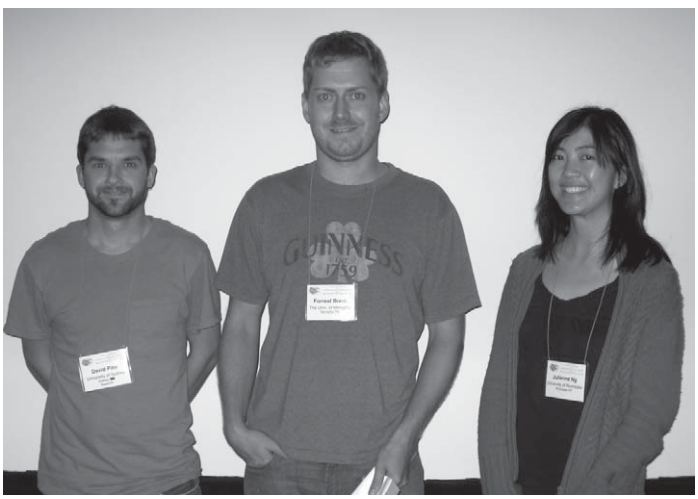
Aaron Bauer conveyed some information about the 2012 WCH in Vancouver (Aug 8–14). The first formal announcement will be made in January, 2011. Aaron indicated that accommodation at a variety of prices ($30–$170 per night) would be available and that registration fees would likely be $350–450 depending on the number of registrants. SSAR has previously indicated that it will participate in this meeting.

There was discussion of implementing page charges for non-members publishing in SSAR journals. Effectively, members are underwriting

the costs of publication by nonmembers. According to Geoff Smith, approximately 40% of papers submitted to *Journal of Herpetology* include at least one author who is a member of SSAR. There was concern that instituting page charges would affect submission rate from nonmembers from outside the United States. The board decided not to impose page charges on nonmembers. Rather, the editor or president would send a copy of the new membership brochure with a letter encouraging joining SSAR to nonmember authors once a manuscript has been accepted for publication.

There was discussion of various ways of encouraging students to participate more in SSAR and of ways to raise funds to support students. One proposal was that we could run a raffle, e.g., for a trip. This will be discussed further with students.

Several minor amendments to the bylaws are necessary because of the switch to electronic voting. The board agreed to send these amendments to the members along with the 2008 ballot.



The proposal to formalize the planning, management and financing of the JMIH was rejected outright by the ASIH Executive Committee earlier in the day, and thus was not considered further by SSAR. The board however recognizes that this is a very important issue and must be addressed.

A balanced budget for 2009 of $277,860 was approved. The meeting was adjourned at 1630 h.

The Annual SSAR Business Meeting was called to order by President McDiarmid at 1618 h on July 26th. Approximately 41 SSAR members were in attendance. In contrast to recent business meetings, each officer, editor, and committee chair in attendance then presented their own annual reports (rather than the president summarizing reports) and relevant information from the board meeting.

Winners of the 2008 Dean Metter Award, Kennedy Award, Henri Seibert Student Awards, Grants in Herpetology Awards, and Student Travel Awards were announced.

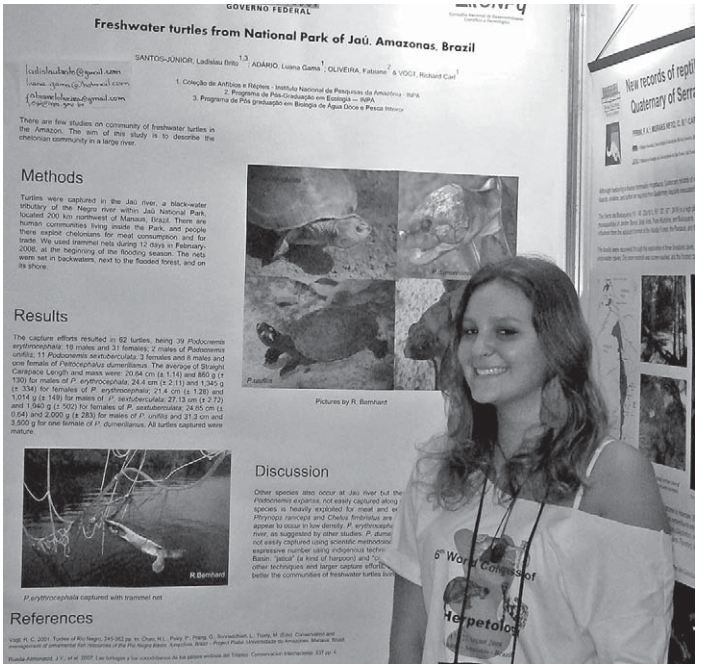
Richard Wassersug (Resolutions Chair) then acknowledged a number of individuals who have served SSAR in a variety of ways. Robin Jung Brown is stepping down as co-editor of *Herpetological Conservation* Vol. 3. Richard mentioned that anyone lucky enough to see a copy of *Urban Herpetology* will appreciate the great effort that went into producing this volume. Richard also acknowledged Breck Bartholomew's contributions to *Herpetological Conservation*, Vol. 2 (*Ecology, Conservation, and Status of Reptiles in Canada*). Breck was instrumental in finalizing and seeing this volume through to press. Managing Editor Tom Tyning was

2008 Henri Seibert Award winners (from L to R) David Pike (Conservation Category), Forrest Brem (Ecology Category), and Juliet Ng (Systematics/Evolution Category). The winners each receive a check for $200 and a book of their choice from UCPress kindly donated by Chuck Crumly. Photo by M. Preest.

The traditional passing of the gavel from President McDiarmid (left) to President-Elect Crother (right) at the end of the Business Meeting. Photo by M. Preest.

thanked for his many years of involvement with *Herpetological Review*. Among other services to SSAR, Tom (along with George Pisani) was instrumental in the conversion to electronic composition of *Herpetological Review* in early 1990s. Michael Burger (Section Editor, Herpetological Husbandry) and Michele Johnson (Section Editor, Current Research) were also thanked, and Richard acknowledged Sarah Bouchard who resigned as Associate Editor for *Journal of Herpetology*. Margaret Gunzburger and Lora Smith, who served as co-chairs of the Seibert Award committee for several years, are stepping down. They were thanked for continuing the tradition of acknowledging papers of high quality presented at the Annual Meetings.

Richard acknowledged on behalf of the society the 50th Anniversary Celebration Committee: Al Savitzky (Chair), Bob Aldridge, Robin Andrews, Jan Caldwell, Jonathan Losos, Roy McDiarmid, Henry Mushinsky, and Kirsten Nicholson. Kraig Adler, Ron Altig, John Applegarth, Breck Bartholomew, Joe Collins, Marty Crump, David Dennis, Bob Hansen, Julian Lee, John Moriarty, Jim Murphy, John Simmons, Geoff Smith, and many, many others also contributed to making this celebration such a success. SSAR wishes to thank Ron Javitch who has been, and continues to be, a major benefactor for our Society activities. He has been a major supporter of SSAR's many publications, including books, the Facsimile series, and *Herpetological Circulars*. He supports the society auctions by donating and bidding on many items.



Henry Mushinsky is stepping down as SSAR representative on the Meeting Management Committee, having served this role for several years. Richard commented that members who have been attending meetings for a couple of decades or so, know that Henry's efforts on behalf of SSAR in regards to meetings extend back beyond his service on this committee. Henry's work on behalf of SSAR (much of which is behind the scenes) is greatly appreciated and the success of these meetings owes much to his labors. SSAR owes a debt of gratitude to Dawn Wilson who guided the Silent Auction for many years (often single-handedly). Although she officially resigned this year as coordinator, she will continue to provide input and guidance to student fund raising activities. Zack Walker recently resigned after serving as webmaster for several years. His designs and efforts greatly improved the web page and raised the society's image. Everyone who worked either directly or indirectly with Zack found him a pleasure to work with. Jim McGuire was thanked for presenting the President's Travelogue on the first evening of the meeting. Richard noted that SSAR depends entirely on volunteers, and the Society as a whole

thanks the many people whose hard work keep SSAR running: the officers, members of the board, chairs and members of various committees, editors of journals plus the associate and section editors they rely on. In regards to our journals, the society also thanks individuals who review the many manuscripts we receive and those who help with the presubmission review of manuscripts by non-English speakers. Finally, Richard thanked those in attendance for coming to the meeting. He noted that it is because of the dedication and hard work of both students and professionals that SSAR is as strong a society as it is.

On a personal note, I would like to acknowledge what a pleasure it has been for me to work with Roy McDiarmid (as it was with previous presidents Janalee Caldwell and Robin Andrews). My job and those of other officers, plus editors and committee chairs, are made so much easier when we have someone as dedicated to the society as Roy is at the helm. Roy is just the tip of the iceberg, however, and as Richard noted, this society has a fantastic group of volunteers many of whom I interact with on a weekly basis. I look forward to working more with Brian Crother when he officially assumes the president's position and I hope SSAR continues to elect presidents who are as committed to the society's future and best interests as those with whom I have had the opportunity to work.

The business meeting ended with the traditional passing of the gavel from outgoing President McDiarmid to President-Elect Crother and was adjourned at 1747 h.

—Respectfully submitted by Marion Preest, SSAR Secretary

Luana, student from Manaus, presenting her turtle poster.

The Sixth World Congress of Herpetology Manaus, Amazonas, Brazil

The Sixth World Congress of Herpetology in Manaus, Amazonas, Brazil took place 17–22 August 2008 and was attended by 565 delegates from 43 countries—greater attendance than for either of the last two World Congresses. North America was represented by 117 (21%) registrants, South and Central America with 256 (45%), Europe with 98 (17%), Asia and Oceania with 83 (15%), and Africa 11 (2%). This cosmopolitan group of herpetologists included 270 professionals, 164 students, 18 accompanying persons, and 110 local committee and support staff. We obviously did not need such a large local committee; however, when I asked for volunteers, the local students from Manaus universities came out in force, willing and eager to participate. I was able to bring them into the participation of the event through grant monies obtained from local, state, and federal Brazilian governmental agencies as well as a generous grant from Conservation International.

The quality of the scientific presentations was outstanding. There were 293 oral presentations including the 15 distinguished plenary lectures, 15 symposia, and contributed oral paper sessions. The poster presentations were held at the end of each day in the book and equipment exhibition room complete with bar service, providing the exchange between the authors and audience in a more relaxed atmosphere. Each day a different group of 50 posters was presented following various themes, most notably genetics, conservation, and ecology. The abstracts were available on line prior to the meeting on the 6WCH web site and also distributed on CD at the meeting in accordance with my ideas initiated at the Joint meeting in 2003 that we do not have to have printed abstracts. However I was forced by the Secretary General of the EC of the WCH to make available some printed abstract books as well. Copies of the 421-page tome are available from me at a 50% discount while they last for US $40 plus shipping.

The meeting got underway early, at 1230 h on Sunday August 17, with the Conservation International sponsored Amphibian Conservation Workshop. The event got a send off pitch from Claude Gascon and Jim Collins, followed by 13 reports from around the world. This well attended event was followed by the first two Plenary Lectures, Bill Magnusson speaking on the evolution of herpetological studies in the Brazilian Amazon and Russ Mittermeier delineating priorities for global reptile and amphibian conservation. This was followed by the opening social in and around one of the swimming pools in Hotel Tropical.

Throughout the week each morning and afternoon session was initiated by a Plenary Presentation followed by six papers in five different lecture rooms simultaneously. One of the most exciting plenary lectures was that of Peter Narins, who enlightened us about the ultrasonic vocalizations that some species of Bornean frogs are making in their mating calls given amidst the din of waterfalls. Thus opening up an entire new dimension in anuran communication studies. How many times have you been sitting next to a silent frog that was actually calling?

Monday afternoon at the poster session we had a 400 capirinha send off for the presentation of two Conservation International financed books: *Las Tortugas y Los Cocodrilianos de Los Paises Andinos del Tropico*, by Jose Vicente Rueda Almonacid et al., and *Field Guide to the Anurans*

Camila Ferrara, James Parham, and Brian Horne with *Podocnemis erythrocephala*.

John Legler mobbed by appreciative students.

of the Pantanal and Surrounding Cerrados, by Masao Uetanabaro et al. Some of the et al. authors of the books were present to sign copies: Russ Mittermeier, John Carr, Dick Vogt, and Domingos de Jesus Rodrigues. At the same time, Vogt also introduced his new books on Amazon turtles published in English, Spanish, and Portuguese as well as *Rainforests*.

Ian Swingland, a meeting Sponsor and the Director of the First World Congress of Herpetology in 1989, invited all of the turtle biologists to his presidential suite for cocktails and munchies on Tuesday evening, it was well attended by professors and students alike.

The rain gods smiled down on the meeting and we were able to have both the picnic on the beach of the Rio Negro complete with live native folkloric dancers and the banquet as well under the stars with no hint of rain.

Meeting participants ventured out on post meeting field trips to Reserva Ducke, Jau Nacional Park, Virua Nacional Park, turtle farms, and up the Rio Negro. A number of turtle biologists accompanied Camila Ferrara and me up the Rio Negro to the Rio Itu and Rio Jaupiri. Here we were able to collect and release a few dozen *Podocnemis erythrocephala* and *P. sextuberculata*, showing our guests the differences between the turtles inhabiting black water and white water habitats. It was a stellar group with three plenary speakers: John Legler, Oscar Flores Villela, and James Parham. Also on board to help lead stimulating discussions about turtle conservation and biology were Brian Horne, Andrew Walde, Gerald Kuchling, Joanna Burger, Glen Gerber, Chuck Schaffer, and Rick Hudson. Juliette Velosoa came all the way from Madagascar to join our trip to compare the habitat of *Peltocephalus* to that of the similar *Erymnochelys* from her native land. The group also had the opportunity to swim with and feed wild pink dolphins in the Rio Negro.

The editors of the electronic journal *Herpetological Conservation and Biology* are soliciting all those who presented posters at either the WCH in Manaus or the Joint Meeting in Montreal to submit notes to be published essentially as presented in the poster. These notes will, of course, have to be submitted to the review process, but most of them should be publishable. Contact Malcolm McCallum for details (e-mail: Malcolm.McCallum@tamut.edu). The plenary speakers are also writing down their thoughts to be published as a volume of the HCB as well. Some of the symposia speakers are organizing their presentations for private publication in hard copy while others will be published in HCB.

I thank you all for attending and making this meeting one of the great ones to remember!

—Dick Vogt, Director 6WCH

NEWSNOTES

Slowinski Award Announced for 2008

The Center for North American Herpetology is pleased to announce that the recipient of The Joseph B. Slowinski Award for Excellence in Snake Systematics for 2008 is Frank T. Burbrink of the College of Staten Island/City University of New York.

On 12 September 2001, the world lost one of its premier herpetologists, a loss that went virtually unnoticed in the wake of the tragedy that befell the United States the previous day. Joseph Bruno Slowinski, the 39 year old curator of herpetology at the California Academy of Sciences in San Francisco, died in the jungles of Burma from the bite of a venomous snake. Joe was bitten on 11 September and succumbed to the effects of the bite the next day. Eventually, the world took notice and media outlets throughout the U.S. and beyond chronicled Joe Slowinski's exemplary career, cut so tragically short.

A distinguished committee, comprised of Simon Creer (University of Wales, Bangor), Hussam Zaher (Museu de Zoologia da Universidade de Sao Paulo, Brazil), and Christopher L. Parkinson (committee chairperson, University of Central Florida, Orlando), has deemed the paper "How and when did Old World ratsnakes disperse into the New World?" published in volume 43 of *Molecular Phylogenetics and Evolution*, as the most distinguished paper on snake systematics to appear during 2007. The paper was co-authored with Robin Lawson (California Academy of Sciences, San Francisco).

As senior author of the paper, Dr. Burbrink becomes the sixth recipient of The Slowinski Award, and will receive a check from The Center for North American Herpetology for US $500 along with a commemorative memento in recognition of his achievement.

2008 Sabin Award for Amphibian Conservation

Sathyabhama Das Biju has been selected from a pool of outstanding candidates from around the world to receive the 2008 Sabin Award for Amphibian Conservation. This award, which is in its second year, was instigated by the Amphibian Specialist Group of IUCN/SSC (http://www.amphibians.org) to recognize an individual or group that has made a significant contribution to amphibian conservation and/or research.

This award recognizes Biju's extreme dedication to discovering and conserving the amphibian fauna of the rapidly vanishing Western Ghats biodiversity hotspot.

For fifteen years, S. D. Biju has been tirelessly working to document the amphibians of the Western Ghats, often using his personal earnings to fund his explorations. His mission: to document and propose conservation priorities through scientific methods. When he started his self-funded research project, he worked as a plant systematist in Tropical Botanic Garden and Research Institute in Kerala. Later, he quit this job to fully focus on frog research, and transferred to the Vrije Universiteit Brussel to obtain a PhD on amphibians of the Western Ghats. He is now leading a research group at the University of Delhi as an associate professor.

When he initiated his research in the Western Ghats, there was very little objective evidence for assessing conservation priorities of the amphibian fauna. Biju conducted over 1000 field visits throughout the Western Ghats and documented over 850 distinct populations of amphibians. Through directed field expeditions, he tracked and re-discovered rare species which were known only from century old descriptions.

After 15 years of exploration and research, Biju has gathered evidence for about 100 species new to science. The discovery and description of an entirely new frog family (Nasikabatrachidae, 'the purple frog'), sent ripples through the entire scientific community and also caught international attention of the popular press. This species was described as 'the coelacanth of frogs' and 'a once in a century find.' Biju's prolific outputs brought a fresh fascination for amphibians among many Indian scientists and forest officials, and provided the push needed to increase the pace of amphibian research in India. The burrowing purple frog also has important conservation implications. Inundation of large chunks of valley forests in the Western Ghats by dam projects could spell disaster to this ancient amphibian and many other endemic taxa. India now has *Nasikabatrachus* to use as a flagship to promote the conservation of important habitats in the region.

SSAR congratulates Dr. Biju on this important recognition.

ICZN Proposal Regarding Electronic Publication of New Names

The International Commission on Zoological Nomenclature (ICZN) rules governing availability of animal names require publication in a durable medium. To date, that has been interpreted as including paper and 'hard' digital media such as CD-ROMs, but this has become increasingly problematic as electronic publication becomes more common. To address this issue the Commission is considering an amendment to the Code that will permit electronic publication of new names and nomenclatural acts. A draft has been published in *Zootaxa*, and will be followed by publication in other journals, including the *Bulletin of Zoological Nomenclature*. This initiates a year-long period for community input, after which a final amendment will be drafted and voted upon by the Commission.

The published draft may be downloaded from the ICZN website (www.iczn.org) or the *Zootaxa* website http://www.mapress.com/zootaxa/.

The summary points are 1) electronic-only publications should be allowed, if mechanisms can be found that give reasonable assurance of the long-term accessibility of the information they contain; 2) some method of registration should be part of the mechanism of allowing electronic publication of names and nomenclatural acts; and 3) works that are not paper-based (e.g., CD-ROMs, DVDs) should be disallowed.

Comments may be addressed to the ICZN through Dr. Ellinor Michel, Executive Secretary (iczn-em@nhm.ac.uk).

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

27–29 March 2009—32nd Annual Herpetology Conference (with 6th Annual Southeastern Ecology and Evolution Conference), Paramount Plaza Hotel and Suites Conference Center, Gainesville, Florida, USA. Sponsored by the University of Florida, Florida Museum of Natural History, and the Reptile and Amphibian Conservation Corps. Information: Benjamin Atkinson (e-mail: bka@ufl.edu).

19–23 April 2009—16th International Conference on Aquatic Invasive Species, Fairmont Queen Elizabeth Hotel, Montreal, Canada. A forum on Bullfrog Eradication and Control will be part of the program. Registration: http://www.icais.org/; information: www.bullfrogcontrol.com.

22–27 July 2009—52nd Annual Meeting, Society for the Study of Amphibians and Reptiles; 89th Annual Meeting, Amercian Society of Ichthyologists and Herpetologists; 67th Annual Meeting, The Herpetologists' League. Portland, Oregon, USA. Information: http://www.dce.ksu.edu/jointmeeting/.

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Aquatic and Terrestrial Egg Laying in a Panamanian Treefrog

Adaptations that have allowed terrestrial oviposition, especially with regard to oxygen uptake and water retention, broadly conflict with the requirements for aquatic egg laying, ensuring that few species are known to display variable reproductive modes. In this study, the authors described the first example of a vertebrate that is able to lay eggs both in the water and on land, the neotropical treefrog, *Dendropsophus ebraccatus* (formerly *Hyla ebraccata*), from Panama. This species was originally thought to lay eggs terrestrially, however, of the 148 clutches laid near a pond at the site of a former gravel quarry, 28% were completely submerged, 48% were laid at the water surface, and 24% were laid terrestri-

ally. This contrasted with exclusively terrestrial egg laying at two nearby ponds. By exposing breeding pairs from each pond to shaded and unshaded breeding sites in a series of experiments, the authors demonstrated that aquatic egg laying was a response to a lack of shade availability, which presumably increases the risk of desiccation. Furthermore, mating pairs could lay both aquatic and terrestrial eggs on the same night, highlighting the plasticity of this response. As this species is basal to a clade of terrestrial breeders within a large lineage of aquatic breeders, the authors conclude that this plastic response is an intermediate form in the evolution of terrestrial egg laying.

Male Moor Frogs do not Lek with Kin

Although most commonly associated with birds, lekking behavior is observed in a number of diverse taxa, including amphibians. A subordinate male may secure relatively more mating opportunities at a lek, simply by being close to more preferred male, or by being in areas that are favored by females. Alternatively, if a subordinate male is closely related to the top males in a lek and large leks attract more females than smaller ones, then kin selected benefits can accrue, without the subordinate male securing matings. In this study, the authors examined the importance of kin selection on lek formation in the Moor Frog, *Rana arvalis*, in Scania, southern Sweden. Eight microsatellite loci were used to determine genetic relatedness of 203 males from seven leks across two populations. The degree of relatedness between males in a lek was found to be low, with leks containing closely related males no more often than would be expected by chance. The authors suggest that lek formation in this species may be a result of two types of female choice. The first type is female choice for breeding aggregations, which due to the high levels of male-male competition characteristic of leks may maximize her chance of mating with a desirable male. The second type is female choice for habitat that is suitable for oviposition.

Threatened Tuatara Species has Reduced MHC Variation

Genes of the major histocompatibility complex (MHC) are an important component of the vertebrate immune system. Due to the way in which these MHC genes function, heterozygotes are thought to be more fit due to their capacity to provide a greater diversity of antigens than homozygotes. The genetic consequences of population bottlenecks at neutral genetic loci have been well studied, however, little work has been done on the impact of bottlenecks on fitness-related genes. Of the two extant species of tuatara, *Sphenodon punctatus* is comprised of two genetic groups divided among several islands, while the only remaining natural population of *Sphenodon guntheri* is on North Brother Island (NBI) in eastern Cook Straight off the coast of New Zealand. Previous work on these populations has shown that *S. guntheri* has low levels of microsatellite diversity compared to *S. punctatus*. In this study, the authors determined the impact of a population bottleneck on fitness-related genes by sequencing regions of the MHC class I exon 2. The NBI population demonstrated significantly reduced MHC variation when compared to a population of *S. punctatus* on nearby Stephens Island. Only three MHC sequences and three (out of a possible six) genotypes were present on NBI, compared to 15 sequences and 21 genotypes in a similar sample size from Stephens Island. The authors conclude that the low MHC diversity observed in NBI tuatara could severely reduce this population's capacity to respond to new diseases.

Ecological Separation in a Polymorphic Salamander

Polymorphic species provide a unique opportunity to investigate the importance of reproductive isolation in sympatric speciation. In this study, the authors examined a polymorphic population of the Red-backed Salamander, *Plethodon cinereus*, in the Cuyahago Valley National Park, Ohio (USA), which is composed of striped and unstriped morphs. Previous studies in this species have demonstrated a correlation between climate and color morphology, however, no studies have examined whether diet and mate choice vary between the color morphs. Mate choice was determined by examining the composition of adult pairs cohabitating beneath ceramic wall tiles placed on the forest floor. Based on the findings of a previous study, cohabitating adults were assumed to be mated pairs. In total, 94 mated pairs were observed, of which 68 were same-color pairs, and 26 were non-matching pairs. Gut analysis was used to determine diet composition, with striped morphs consuming a more varied and profitable diet than unstriped morphs. Additionally, in agreement with previous studies in this species, the authors found that unstriped morphs withdrew from the forest floor when temperatures fell earlier than striped morphs. Despite the observed ecological separation, and the observed incidence of selective mating, the authors suggest that due to the level of intermorph matings, they are unlikely to be undergoing divergence. However, as the morphs respond differently to environmental conditions, climate warming may open new niches which could encourage future divergence in this species.

Impact of Agriculture on Reproduction in the Toad, *Bufo marinus*

Studies of the impact of pollutants on wildlife commonly have compared polluted and unpolluted sites. However, as pollutants can be transported hundreds of miles from the point of application, essentially no site can be considered completely pollutant free. In this study, the authors examined gonadal function and abnormalities in *Bufo marinus* from south Florida, USA, from five sites that differed in intensity of agricultural land use. There was an increased frequency of intersex individuals (specimens exhibiting both female and male reproductive tissue) from the two most agricultural sites. By examining the extent of male and female reproductive tissue within intersex toads, the authors were also able to quantify the severity of the intersexed condition, and found that toads became more intersexed as agriculture increased. Furthermore, secondary sexual traits, such as skin color, nuptial pad number and forearm width were all altered in toads from the highly agricultural sites. The authors suggest that these intersex toads are feminized and demasculinized male toads. Finally, they conclude that as agricultural chemicals are distributed globally, and appear to illicit a dose dependent response on reproductive function, they may be linked to amphibian population declines.

Male Responses to Aggressive and Submissive Signals in the Jacky Dragon

Intraspecific conflict over resources can be costly for both winners and losers, both in terms of energy expended as well as increased risk of injury or vulnerability to predation. These significant costs have led to the evolution of non-combative conflict resolution, a common example of which involves an individual dynamically signaling their fighting ability and motivation. The Australian jacky dragon, *Amphibolurus muricatus*, displays a number of signaling behaviors, with males commonly performing a stereotyped push-up display, which has been shown to play a part in opponent assessment. Previous research has also demonstrated that two other behaviors, slow arm-waves and slow head-bows, signal submission in conflict situations. In this study, the authors used interactive video playback of an animated stimulus lizard, which allowed them to examine responses to these different behaviors while controlling for signaler morphology. Five display animations were produced, each starting with a series of push-up displays. In the control treatment, the animated lizard then displayed a number of substrate licks. In the "aggressive" treatment, the animated lizard responded to all behaviors of the focal male with push-up displays. In the "submissive" treatment, all behaviors were matched with slow arm-waves. A "matching" treatment, where the behavior of the focal male was matched by the animation, and an "opposite" treatment were also produced. The aggressive treatment failed to suppress attacks as compared to the control treatment, and the submissive treatment actually increased the rate of attack. Interestingly, attacks were frequent when the animated male responded to a submissive display by the focal male, suggesting that behaviors are monitored closely and are sensitive to social contingencies.

Boldness Linked to Foraging Success in an Invasive Gecko

Lepidodactylus lugubris, a parthenogenetic gecko that arose from the hybridization of two sexual species from the Marshall Islands, is now widespread throughout the Pacific Islands. There are four major clone lineages that differ ecologically, and are thought to have arisen from independent hybridization events. Since the mid-1990s, *A-clones* have become the most common clone, increasing in both abundance and distribution. In this study, the authors investigated whether *A-clones* are displacing *B-clones* due to behavioral differences related to foraging success and aggression. *A-* and *B-clones* were selected from a laboratory-reared population that had been captured one generation previously from Oahu, Hawaii. Geckos were placed in one of two experimental enclosures, one which, in addition to a shelter, contained a number of opaque plastic barriers designed to add to the structure of the environment. The other enclosure was of equal size, but contained only a shelter. A number of behavioral variables were measured, including foraging attempts, total consumption and activity. *A-clones* were superior foragers, having greater consumption and a reduced time to first successful foraging attempt, and did so at the expense of *B-clones*. Interestingly, *A-clones* displayed lower levels of activity than *B-clones* overall; however, *B-clones* used and defended shelters more frequently. The complexity of the habitat affected foraging, aggression and activity levels in both clones, with *A-clones* remaining superior foragers in both treatments. The authors conclude that the increased use and defense of shelters by *B-clones* may explain their persistence in structurally complex habitat, such as forests. In contrast, *A-clones* have an advantage in structurally simple environments, such as human landscapes, due to their innate boldness perhaps enabling them to exploit scarce food resources.

Uncovering the Introduction History of Australian Bell Frogs into New Zealand

Two species of Australian bell frogs, *Litoria raniformis* and *L. aurea*, were introduced into New Zealand in the late 1800s to control mosquito larvae and provide food for ducks. Despite these two species now being threatened in Australia, they are widespread and abundant in New Zealand. As both the precise release locations and the source populations for introduced frogs are unknown, the authors of this study have used molecular techniques to investigate the introduction history of bell frogs in New Zealand. Partial sequences of the mitochondrial DNA region cytochrome oxidase I were obtained from across the native range of both species. Results of the molecular analyses indicated that *L. aurea* was introduced from two areas of Australia, northern and southern coastal New South Wales, and into the North Island of New Zealand. *L. raniformis* was introduced from the vicinity of Melbourne, Victoria, and into New Zealand's South Island, from which they dispersed to the North Island. Previously, it was thought the *L. raniformis* was introduced into New Zealand from Tasmania, however this hypothesis was rejected. Finally, the authors observed extremely diverse mitochondrial lineages in *L. raniformis* within mainland Australia, perhaps pointing to the existence of a cryptic species.

Vörös, J., A. Mitchell, B. Waldman, S. Goldstien and N. J. Gemmell. 2008. Crossing the Tasman Sea: Inferring the introduction history of *Litoria aurea* and *Litoria raniformis* (Anura: Hylidae) from Australia into New Zealand. Austral Ecology 33:623–629.

Horned Lizards Use Mucus to Incapacitate Dangerous Prey

Horned lizards, genus *Phrynosoma*, feed almost exclusively on ants, in particular, the venomous harvester ants (genus *Pogonomyrex*). Unlike most other lizard species that consume dangerous prey, horned lizards do not incapacitate their prey by biting or chewing. Instead, they combine prey capture, transport and swallowing into a single stage. In this study, the authors examined how horned lizards are able to consume dangerous prey without first incapacitating them mechanically. It was found that horned lizards possess unique pharyngeal papillae that secrete mucus which incapacitates and immobilizes prey. More mucus secreting folds exist in the esophagus which the ants pass through as they are consumed. Ants examined from the gut of horned lizards were bound in mucus and curled into balls. The authors suggest that by using mucus to incapacitate dangerous prey, horned lizards are able to consume a larger number of ants in a single feeding bout. This reduces the chance of being attacked by predators while feeding or being detected by the ant colony and being mobbed by aggressive worker ants. The authors suggest that this feeding adaptation may be one result of an ongoing co-evolutionary relationship between harvester ants and horned lizards.

Sherbrooke, W. C., and K. Schwenk. 2008. Horned lizards (*Phrynosoma*) incapacitate dangerous ant prey with mucus. Journal of Experimental Zoology 309A:447–459.

Lizards from Rocky Habitats Evolve a Flatter Body Plan

The occurrence of similar morphological traits among unrelated organisms from similar habitats has often been used as evidence of convergent evolutionary change. For example, many unrelated lizard species display head and body flattening that appears associated with the use of vertical rocky habitats. However, whether this morphology is solely the result of the occupation of rocky habitats has never been rigorously tested. Using phylogenetic comparative methods, the authors examined 18 tropical skink species from northeast Queensland that occupy three broad habitat categories (generalist, leaf litter, rock-dwelling) to test whether the observed patterns of morphological convergence in this lizard clade are related to the use of rocky habitats. This work revealed that despite relatively few morphological differences overall, rock-using species have consistently and repeatedly evolved a dorsoventrally flattened body and head. This study highlights the role of rocky habitats in driving adaptive shifts in morphology that is likely associated with increased selection on enhanced running and climbing performance, movement into and within rock crevices, and improved camouflage of species from rocky habitats.

Goodman, B. A., and J. L. Isaac. 2008. Convergent body flattening in a clade of tropical rock-using skinks (Scincidae: Lygosominae). Biological Journal of the Linnaean Society 94:399–411.

Amphibians: On the Leading Edge of a Sixth Mass Extinction

The history of life on earth has been punctuated by periodic extinction events that saw as many as 95% of all species become extinct. Many researchers have suggested that we are currently experiencing a biodiversity crisis on par with past extinction events. The authors set out to examine this hypothesis from an amphibian perspective. Amphibian species are widely understood to be disproportionately threatened relative to other taxonomic groups. As of 2004, 32.5% of known amphibian species were "globally threatened," as calculated by the Global Amphibian Assessment. In this article, the authors detail amphibian declines in California's Sierra Nevada and the Central American Highlands. These case studies exemplify how numerous factors, climate change and infectious disease (chytridiomycosis) in particular, are acting in concert to push amphibian species to the brink of extinction and beyond. The tropics are of special concern as they are high in amphibian richness, are home to species with smaller distributions relative to temperate species, and are experiencing extreme rates of habitat conversion. The authors conclude that we are in the midst of an amphibian mass extinction event, as current extinction rates are 221 times higher than background rates. Furthermore, they conclude that humans are ultimately responsible for this mass extinction event.

WAKE, D. B., AND V. T. VREDENBURG. 2008. Are we in the midst of the sixth mass extinction? A view from the world of amphibians. PNAS 105:11466-11473.

Bert Langerwerf (1944–2008): Lizard Breeder Extraordinaire

RUSS GURLEY
Living Art Publishing
Turtle and Tortoise Preservation Group
114 E. Kings Road, Ada, Oklahoma 74820, USA
e-mail: russgurley@cableone.net

and
RONALD L. TREMPER
Center for Reptile and Amphibian Propagation
217 Upper Cibolo Creek Road, Boerne, Texas 78006, USA
e-mail: rtremper@gvtc.com

Renowned herpetoculturist Bert Langerwerf passed away on 11 August 2008 following a courageous battle with cancer. Bert was born on 28 February 1944 in Waspik, Netherlands, on his father's birthday. Bert's father, Wilhelmus Langerwerf, was a farmer; his mother, Coralie, was the youngest daughter of a boatman. Various aunts and uncles lived on boats that transported goods, mostly coal and other raw materials, along the Rhine River from Basel to Rotterdam.

Although Bert was formally educated at the University of Amsterdam and subsequently taught physics at Dr Mollercollege in Waalwijk, his passion was lizards. He recalled catching his first lizard as a nine-year-old during a break from a soccer game at school: "It was a nice warm day in May and there was a dry ditch at the northern edge of the soccer field. I went to look for animals in that dry ditch. Rush…there ran a lizard! A real lizard being chased by me on the sunny southern slope of that dry ditch. Out of excitement I did not hear the shouting boys anymore, but rather a kind of music, when I found my first lizard. I followed the lizard and caught it without breaking its tail. I reached for my shoe, took off a sock, and put the shoe on again. The lizard went inside the sock and I was rushing home, forgetting everything else. I guess they may have missed me the rest of that school day. A few months later the lizard, a *Zootoca vivipara*, died in a glass jar, and with that I learned that I did something wrong, because I wanted to keep the lizard alive."

Bert Langerwerf, up a tree, surveying the hundreds of outdoor terraria at Agama International, in 2000.

Bert built his first outdoor terrarium in 1954 and joined the Dutch Club for Terrarium Keepers in 1958. Since these early days, he has maintained memberships in herpetological societies around the world, and has spoken to local reptile clubs, as well as scientific herpetological societies in the U.S. and Europe.

Aside from lizards, Bert's other passions were music and languages; he was fluent in English, Dutch, German, French, Spanish, Italian, Danish, Finnish, Swedish, and Russian, and still learning more. He enjoyed the music of the exotic places associated with his searches for lizards, often treating his traveling companions to the music of Morocco, Egypt, Russia, Finland, and elsewhere—played loudly given his near-deafness in recent years.

Bert's early love of lizards grew into his life's work. Over the years, he traveled the world searching for lizards to establish in captivity. Although best known for his work with Argentine Tegus, Australian Water Dragons, Prehensile Tailed Skinks, and Chinese Crocodile Lizards, he successfully bred over 135 species of lizards, turtles, and amphibians, and for some time he was the only private individual to maintain tuatara in captivity.

In 1982, Bert made his first trip to the U.S. to speak at the annual meeting of SSAR in Raleigh, North Carolina. There he met many herpetologists, including long-time friends Sean McKeown and RLT, who would later be influential in Bert's decision to move to the States.

In 1985, Bert took his family from their native Netherlands to Gran Canaria, Canary Islands, where he dreamed of building a lizard breeding facility and zoo. Within two years, Reptilandia—the world's first reptile park—was born. Soon thereafter, however, the Langerwerf family moved again, traveling to New Zealand.

By 1989, at the urging of friends, Bert and family moved to a seven-acre farm near Birmingham, Alabama, where he established Agama International Herpetocultural Institute. Here, he was able to reach full stride, as his lizards thrived in the warm, humid climate of Alabama. Bert constructed over 400 outdoor terraria and numerous outbuildings, all built with his own two hands and simple tools. But the daily operation of the facility was a family affair and a path that few people will ever fully know.

Over the course of his career, Bert made several important discoveries. These included his observations of Temperature-dependent Sex Determination (TSD) in a number of lizard species. He was among the first to recognize the critical role of ultraviolet light in successful husbandry of diurnal lizards. And he was a pioneer in the captive breeding of numerous lizard species. In recent years, Bert spent a great deal of time traveling to conferences and speaking about his advancements and discoveries in lizard behavior, nutrition, lighting, thermoregulation, and reproduction. His travels found him in the company of the world's leading herpetologists and herpetoculturists, many of whom called him friend and col-

league for decades.

Bert is survived by his mother, Coralie Poppelier Langerwerf (age 100), Hester, his wife of 39 years, and sons Aleksis and Timo.

Bert was a truly unique character—brilliant, obsessively focused, innovative, generous, and funny. Surely there will not be another like him. His passion has been an inspiration to us all.

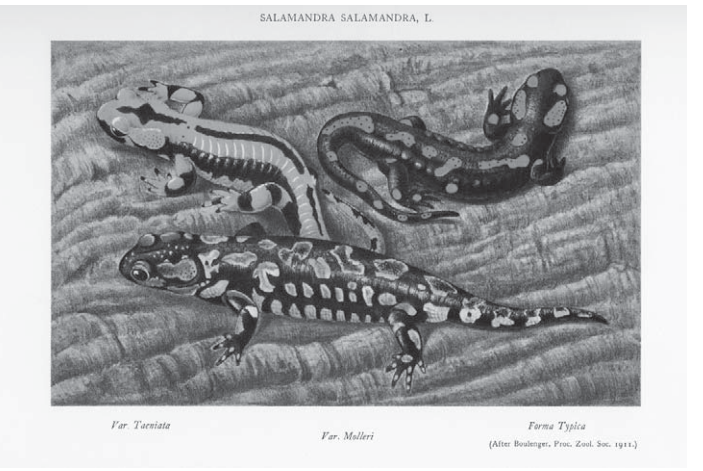
DR. JOHN FERRAIR DESCRIBING BIBLIOMANIA IN *A GENTLE MADNESS: BIBLIOPHILES, BIBLIOMANES, AND THE ETERNAL PASSION FOR BOOKS*, BY NICHOLAS A. BASBANES, 1995.

Medical Management

Every so often, a book arrives on the scene that is destined to become a classic and that time has come again. Elliott R. Jacobson, professor of zoological medicine in the Department of Small Animal Clinical Services in the College of Veterinary Medicine at the University of Florida, has compiled a book of such scope and magnitude that it will likely grace the reference library collection of virtually every veterinarian and pathologist working with reptiles. The first chapter on biology, anatomy, and histology is particularly valuable for the herpetologist as there are many pictures of skulls and a variety of skeletal preparations with major bones identified. Jacobson's book, *Infectious Diseases and Pathology of Reptiles: Color Atlas and Text* (2007, CRC Press, Boca Raton, Florida, ISBN 10:0-8493-2321-5, ISBN 13:978-0-8493-2321-8), is truly awesome: 716 pages, with approximately 1400 high-quality color images. The thirteen chapters, some written by other experts, cover the following topics: reptile biology, anatomy, and histology; immunology; circulating inflammatory cells; necropsy techniques; host response to infectious agents and identification of pathogens in tissue section; identifying pathogens using electron microscopy; molecular diagnostics; serodiagnostics; viruses and viral diseases; bacterial diseases; mycotic diseases; parasites and parasitic diseases; and isolation of pathogens.

Elliott Jacobson's new book is the most detailed reference on infectious diseases and pathology.



Captive Management of Salamanders

On 20 September 2005, a meeting was held at Conservation International in Washington, DC to explore the need to develop assurance colonies for imperiled amphibians. One of the presenters was Jean Raffaëlli, recognized as one of the world's leading authorities on the captive management of salamanders and newts. I was impressed by his talk, accompanied by photos of breeding urodeles living in state-of-the-art enclosures. Later, he contributed to the captive breeding chapter of the Amphibian Conservation Action Plan (ACAP), headed by Joe Mendelson of Zoo Atlanta.

Written in French, Raffaëlli's book *Les Urodèles du Monde* (2007; Penclen Edition; ISBN 978-2-9528246-0-6) has now appeared and sets the standard for a book of this type. In my view, it is the best multispecies salamander book available, covering all species described at the time of publication.

In the first part, Raffaëlli describes his travels around the globe, relating his field experiences and the number of prominent amphibian biologists he encountered. In the next part, his detailed study of some 650 forms of urodeles appears which includes almost all temperate taxa and several tropical species—304 pages of descriptions of families, genera, and species—featuring maps (over 500) and species accounts describing their taxonomy, biology, ecology, behavior, and sections on maintenance and breeding in captivity (Notes d´ élevage). The book has 515 photographs, most in color. The bibliography alone is worth the price of the book. This guide will be of immense value to serious amateurs, such as those in the French Urodela Group (FUG), and professionals alike who wish to learn more about taxonomy, biology, and ecology of salamanders and also how to keep these amphibians alive and well.

The book can be purchased directly from the author (e-mail: jean.

Each of these three examples of Fire Salamander *Salamandra salamandra* was drawn from a living specimen by artist John Green. This was originally a colored illustration from *Anatomy of the Salamander* by Eric T. B. Francis in 1934, slightly modified from Edward G. Boulenger's paper in Proc. Zool. Soc. London 1911. Boulenger was curator of reptiles at the London Zoo beginning in 1911.

Conservation

Believing that virtually all large mammals throughout Asia and Africa are inevitably going to become extinct during this century, Donlan et al. (2005. Re-wilding North America. Nature 436:913–914) proposed a plan to restore predators and prey that disappeared 13,000 years ago from Pleistocene North America. They proposed using extant representatives as genetic reservoirs of ancestral stock to bring about this new radiation—African Lions, African Cheetahs, Asian and African elephants, horses, asses, and Bactrian Camels, but also the endangered Bolson Tortoise (*Gopherus flavomarginatus*)—a taxon which lived across the Chihuahuan Desert in North America during the Late Pleistocene. Presently, Bolson Tortoises are restricted to a limited area in northern Mexico. In the view of Donlan et al., North America offers the best option for establishing these colonies, comprising both predators and prey, on public lands and private game ranches.

If zoo workers are going to ever be asked to embrace the plan to produce hundreds of Bolson Tortoises—or other herps related to ancestors long gone—to populate protected tracts of land in order to support this alternative conservation strategy, this handy reference might help—*Rewilding North America: A Vision for Conservation in the 21st Century*, by Dave Forman (2004, Island Press; Washington, Covelo, London; ISBN 1-55963-060-4 [cloth]; ISBN 1-55963-061-2 [paper]), divided into three main parts: bad news, good news, and taking action.

The Wildlife Conservation Society (WCS), headquartered at the Bronx Zoo, was long led by William G. Conway, who retired as Director of the then New York Zoological Society. WCS has long supported a number of field researchers engaged in studies focused on conservation and habitat protection throughout the world. Conway is internationally known for his leadership and vision, writing one of the classic works in zoo philosophy in 1973: "How to exhibit a bullfrog: a bed-time story for zoo men." (Int. Zoo Yearb. 13:221–226).

In *Act III in Patagonia: People and Wildlife* (2005, Island Press, Washington, Covelo CA, London; ISBN 1-55963-518-5 [hardbound]), Conway explores 12,000 years in Patagonia (Act I), describes Hunting's High Tide (Act II), and summarizes The Road to Conservation (Act III). This is an important and graceful read written by one of the pillars of zoo conservation.

William Conway holding a James's Flamingo in the Chilean Andes at 14,800 feet in 1960. *From Gathering of Animals: An Unconventional History of the New York Zoological Society*, by William Bridges, 1974.

Imprint: New York, Harper & Row.

I admire Michael Lannoo. He is certainly one of the most productive and influential herpetologists in highlighting amphibian declines and the need for dramatic conservation measures. In 1998, he edited *Status and Conservation of Midwestern Amphibians* (Iowa City: University of Iowa Press; ISBN 0-87745-631-3). Seven years later, he produced a volume of such scope that it will clearly be the definitive reference for years to come: *Amphibian Declines: The Conservation Status of United States Species* (2005, Berkeley: University of California Press, ISBN 0-520-23592-4 [hardbound]). Imagine coordinating 215 contributing authors, reviewing over 50 chapters, and compiling species accounts for all of the US taxa—resulting in a volume of nearly 1100 pages. He succeeded brilliantly at this monumental task.

Most herpetologists would sit back and enjoy the fruits of their labor but not Lannoo. He has produced yet another volume—*Malformed Frogs. The Collapse of Aquatic Ecosystems* (2008, Berkeley: University of California Press; ISBN 978-0-520-25588-3). Using data from ecology, parasitology, and other disciplines, he outlines the possible causes of these deformities, identifies which amphibians have been affected, and addresses questions about what these malformations might mean to human populations. Lannoo paints a grim picture, identifying the particulars in the usual litany of causes: chemical, nutrient, and pesticide runoff into wetlands. If this book's title and content are not terrifying enough to attract the attention of citizens, politicians, and policy-makers globally, then one must wonder what type of ecological disaster it will take for humans to pay attention to the perilous state of our world and begin to take steps to remediate the inevitable disasters looming.

Deformed anurans have been reported from Europe as well. Jean Rostand described and pictured a number in the book *Les anomalies des amphibiens anoures* (Paris, Société d'edition d'enseignement supérieur, 1958). The species depicted were Midwife Toad (*Alytes obstetricans*), Edible Frog (*Rana esculenta*), European Common Frog (*Rana temporaria*), and Common European Toad (*Bufo bufo*). Some of the most grotesque anomalies imaginable are shown in figures 12–14, 22, 29, 31, 34, and 37.

In his book *The Windward Road*, the late Archie Carr tells us of his fondness for frogs: "I have always liked frogs. I liked them since before I ever took up zoology as a profession; and nothing I have had to learn about them since has marred the attachment. I like the 'looks' of frogs and their outlook, and especially the way they get together in wet places on warm nights and sing about sex." If Carr would have had the opportunity to read Lannoo's books before he died, he would be saddened to learn that there are far fewer places where he could hear frogs sing.

Is it too late for amphibians? Every zoo biologist must immediately read this paper: Wake, D. B., and V. T. Vredenburg. 2008. Are we in the midst of the sixth mass extinction? A view from the world of amphib-

As aquatic ecosystems collapse around us, the Mudpuppy (*Necturus maculosus*) is particularly at risk, although malformations have not been reported for this taxon. This amphibian has a broad geographical range but populations have declined in Maryland, Indiana, North Carolina, and Iowa, due in part to chemical pollutants, increased siltation, and widespread use as fish bait. Illustration from Georges-Louis Duvernoy's *La Règne Animal par Georges Cuvier, Reptiles volume. Disciple edition. Paris 1842*. This image (plate 41 in vol. 6.) is from the Disciple's edition of Cuvier, published in Paris after his death by his students (i.e., disciples). The herpetology volumes (text plus atlas) are by Duvernoy. Credit: Courtesy of Kraig Adler.

Biographies

In a book entitled *The Remarkable Life of William Beebe: Explorer and Naturalist* (2004, Island Press, Washington, Covelo CA, London; ISBN I-55963-858-3 [softbound]), author Carol Grant Gould has written an account equal to Beebe's extraordinary personal and professional life. In 1899, he began working at the Bronx Zoo (New York Zoological Society). The relationship among the three famous department heads at that time, J. Alden Loring (mammalogy), Raymond L. Ditmars (herpetology), and Beebe (ornithology), was described by Gould: "Despite vast differences in their educational backgrounds, the three young assistant curators got along well. They shared powerful common interests, and each had idiosyncratic skills and areas of special knowledge to share."

Ornithologist Beebe, although most often associated with the Society's Tropical Research Station in South America, published a number of papers in herpetology. Some of the subjects included preparation of snake skins, his unsuccessful attempts to collect lizards with a net in St. Thomas until a young girl taught him how to use a noose, encounter with a bushmaster in South America, Amphibia and Reptilia of the Bartica District, reptiles of the Galápagos Islands, habits of garter and ribbon snakes, development of the toad, sea snakes, and field notes on the lizards and snakes of British Guiana and Venezuela.

William Beebe dressed in expedition garb in British Guiana in 1917. From *Gathering of Animals; An Unconventional History of the New York Zoological Society*, by William Bridges, 1974.

Albertus Seba: In the 1500s, wealthy Europeans had large collections of preserved animals, including many herpetological treasures. Explorers were traveling the world to bring artifacts to Europe. Collectors searched for examples of rare and wondrous objects to place in these cabinets that exemplified the Renaissance search for knowledge and understanding of the world. These collections were called "cabinets of curiosities"—also known as Wunderkammern, or cabinets of wonder—reflecting both the trait of curiosity that drives human search for knowledge, and the extraordinary qualities of the objects in the cabinets. These private cabinets held biological treasures, arranged in no particular order, to excite wonder—monsters or other natural oddities such as a two-headed calf, animals with extra or missing legs, human birth defects, or a horned horse.

A reasonably priced book presents the collection of Albertus Seba in *Cabinet of Natural Curiosities: Locupletissimi rerum naturalium thesauri 1734–1765: based on the copy in the Koninklijke Bibliotheek, The Hague* (2006, published by Barnes & Noble, Inc. by arrangement with Taschen GmbH, Köln; London; ISBN 13:978-0-7607-8204-0; ISBN 10:0-7607-8204-0). Although it is believed by some that zoo workers are notoriously well-paid, a hand-colored original is likely beyond reach—according to Kraig Adler, the last copy offered fetched a sum of nearly US $500,000! This is a fine reproduction of one of the classic natural history books of all time, with nearly 450 plates shown in color. In the introduction, Seba's life and collection of natural history specimens are described.

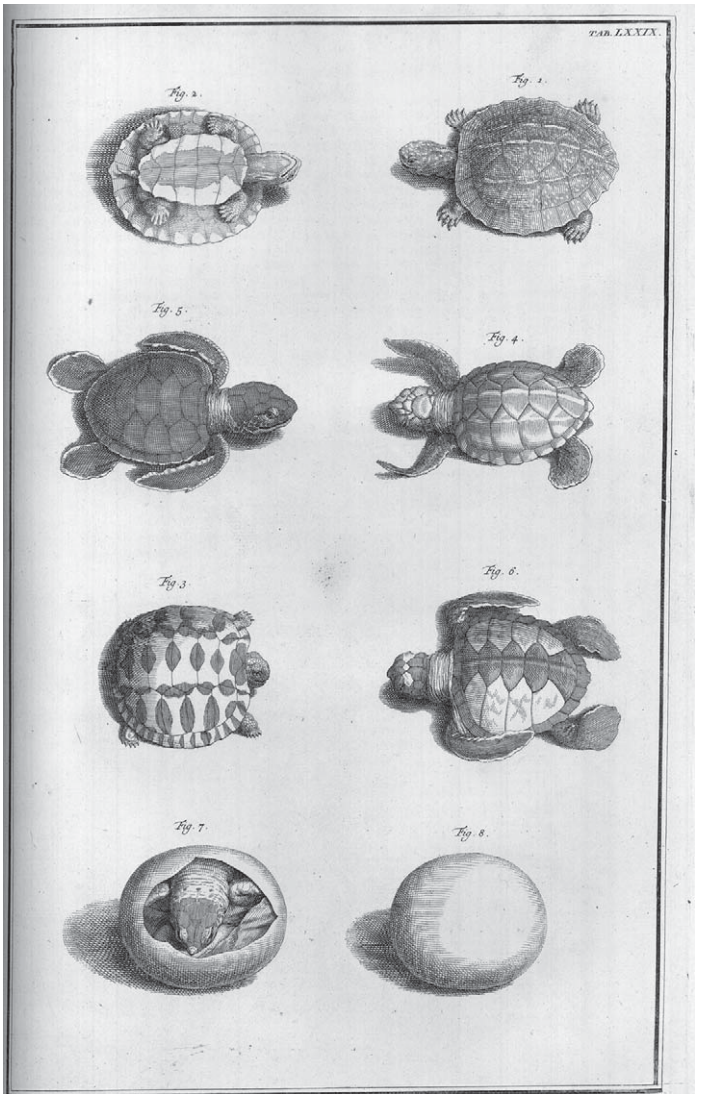

Illustration of chelonian neonates and eggs from Albertus Seba's *Locupletissimi rerum naturalium thesauri accurata descriptio, et iconibus artificiosissimis expressio, per universam physices historiam : Opus, cui, in hoc rerum genere, nullum par exstitit / / Ex toto terrarum orbe collegit, digessit, descripsit, et depingendum curavit Albertus Seba ….*

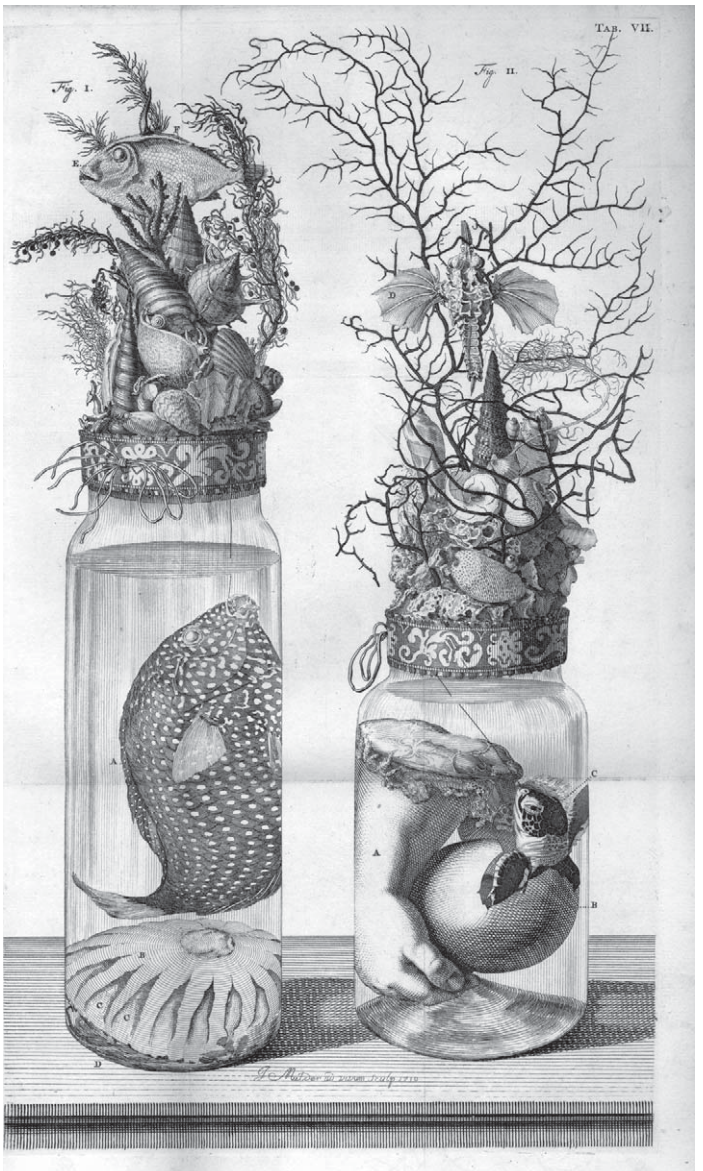

Imprint: Amstelaedami: Apud J. Wetstenium, & Gul. Smith, & Janssonio-Waesbergios, 1734–1765.

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

Joseph Bruno 'Joe' Slowinski: Slowinski, an American herpetologist who worked extensively with elapid snakes, died in an isolated region in northern Burma (Myanmar) after being bitten by a small Multi-Banded Krait (*Bungarus multicinctus*) in 2001. A detailed account of his life and career has recently been published in a book by Jamie James entitled *The Snake Charmer: A Life and Death in Pursuit of Knowledge* (2008,

Hyperion Press, New York; ISBN 13:978-1-4013-0213-0). James' narrative begins with Slowinski's early childhood, development of interest in natural history, and subsequent career as a postdoctoral student working at the National Museum of Natural History and Louisiana State University. He eventually took a position as professor of biology at Southeastern Louisiana University until his dream job opened—curator for the Department of Herpetology for the California Academy of Sciences.

The account of his envenomation and the heroic measures taken by his companions to try and save him for 30 hrs was tough reading, certainly not to be used as a light bedtime distraction before sleeping. James does a masterful job of treating Joe as the complex person he was, especially about his approach to catching venomous snakes. I am not sure how I feel about Joe and his escapades—clearly he was a gifted, productive person but, oh, so careless and reckless with venomous snakes. Because

In this peculiar image from Frederik Ruysch's natural history cabinet in 1710, a human's severed arm and hand holding a sea turtle emerging from an egg in a bottle of preservative is displayed—*Frederici Ruischii . . . Thesaurus animalium primus = / Het eerste cabinet der dieren / van Frederick Ruysch . . .*

This hand-colored woodcut is reproduced from the first illustrated surgical book, *Buch der C[h]irurgia* (Book of Surgery), published in 1497 by Hieronymus Brunschwig. Three doctors are attending to a victim bitten by a viper encircling the leg. Credit: provided by Kraig Adler.

I worked with dangerous snakes in a zoo for over 30 years without a bite, I am amazed at how cavalier he was about the dangers; in fact, we talked several times at herpetological meetings about the danger of working with venomous snakes, especially elapids, and the precautions needed to work safely with them. Although Joe suffered eight bites and many close calls, he continued to free-handle them.

This statement in Joe's article in *California Wild* in 2000 was pro-

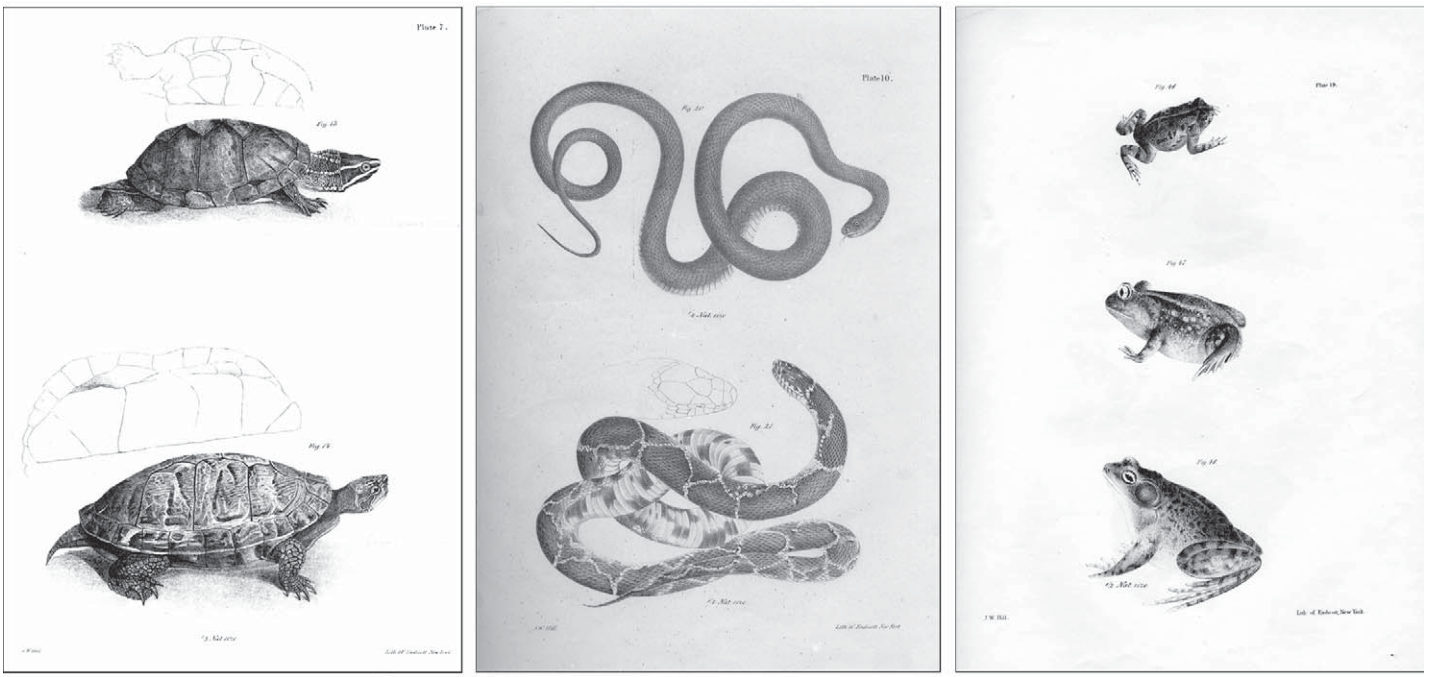
Drawing by R. Mintern of Common Basilisk (*Basiliscus vittatus*) from Albert Carl Ludwig Gotthilf Günther's *Biologia Centrali-Americana*. [vol. 7], Reptilia and Batrachia, 1885–1902.

Imprint: London, Pub. for the editors by R. H. Porter.

phetic, "Neurotoxic proteins are extremely effective at bringing about death with minimal disturbance to the body. Viperid venoms, on the other hand, are messy—tearing apart tissue and literally melting cells. So an elapid venom is more likely to kill you but will leave a far prettier corpse." The picture facing page 180 with Joe next to the Burmese Spitting Cobra (*Naja madalayensis*), a taxon he described, pretty much sums it up—why wasn't he wearing a welder's mask or goggles to protect his eyes instead of those small sunglasses, especially because he had experienced several episodes when snakes had directed a stream of venom toward him?

For anyone working with dangerous reptiles, use this book as a cautionary tale and be bloody careful—that juvenile krait was less than 10 inches long!

Herpetofauna of Honduras



In 1969, John R. Meyer finished his dissertation, *A Biogeographic Study of the Amphibians and Reptiles of Honduras*. Thirteen years later, a book appeared called *The Snakes of Honduras* by Larry David Wilson and Meyer (Milwaukee Public Museum, Milwaukee, Wisconsin; followed by a second edition in 1985). From that time on, the amphibians and reptiles of Honduras and surrounding islands have been featured in a number of papers, mostly written by Wilson, Meyer, James R. McCranie, and Gunther Köhler.

Four excellent books have been published on Honduras in the new millennium. The first is *The Amphibians of Honduras* (2002, Society for the Study of Amphibians and Reptiles; Salt Lake City, Utah; ISBN 0-916984-57-5 [hardbound]) by James R. McCranie and Larry David Wilson with a foreword by Jay M. Savage. This is a large book—625 pages, 126 maps and figures, 33 tables and 20 color plates.

The next year, Gunther Köhler's *Reptiles of Central America* (Herpeton Verlag, Offenbach, Germany; ISBN 3-936180-02-4 [hardbound]) became available with a foreword by Wilson. A prolific author, most of Köhler's work has centered in Central America and this book covers the reptiles occurring from the Isthmus of Tehuantepec in Mexico to the southern extent of the Panamanian isthmus.

The next book is *The Amphibians & Reptiles of the Bay Islands and Cayos Cochinos, Honduras* (2005, Bibliomania, Salt Lake City, Utah; ISBN 1-932871-07-1 [hardbound]) by James R. McCranie, Larry David Wilson, and Gunther Köhler with a foreword by John R. Meyer.

The latest book is *The Amphibians & Reptiles of Cusuco National Park Honduras / Los Anfibios y Reptiles del Parque Nacional Cusuco Honduras*, by Josiah H. Townsend and Larry David Wilson (2008, Bibliomania, Salt Lake City, Utah; translated by Pauline M. Kulstad; ISBN 978-1-932871-12-8). Like so many other cloud forest herpetofaunal assemblages, this one is at risk. The authors put it this way, "…we predict that with continued human population growth, Cusuco National Park will come under increasing pressure from subsistence farming and urbanization." Each taxon account in Spanish and English includes common name, holotype specimen and type locality, similar species, description, distribution, localities in Cusuco, natural history, conservation status, remarks, and references. Rather than using a map to identify all named localities, a gazetteer is provided. Again, this fine book matches the qualities of the other books on Honduras except for maps—illustrated keys, readable text, splendid color photographs, and glossary.

The University of Georgia Press has published several books since 2005 which cover the amphibians and reptiles of the southeastern United States and some representatives are pictured here. These plates are by artist J. W. Hill from James Ellsworth De Kay's *Zoology of New York, or the New-York Fauna: comprising detailed descriptions of all the animals hitherto observed within the state of New York, with brief notices of those occasionally found near its borders, and accompanied by appropriate illustrations*, 1842–1844.

Imprint: Albany, New York, W. and A. White and J. Visscher.

Series: Natural history of New York.

Plate 7 shows the Musk Tortoise (*Sternothœrus odoratus*, now *Sternotherus odoratus*) above and Red-Bellied Tortoise (*Emys rubriventris*, now *Pseudemys rubriventris*); Plate 10 depicts the Black Snake (*Coluber constrictor*) above and Chain Snake (*Coluber getulus*, now *Lampropeltis getula*); Plate 19 includes Common Toad (*Bufo americanus*, now *Anaxyrus americanus*), Hermit Spade-Foot (*Scaphiopus solitarius*, now *Scaphiopus holbrookii*) and Bullfrog (*Rana pipiens*, now *Lithobates catesbeianus*) from top to bottom.

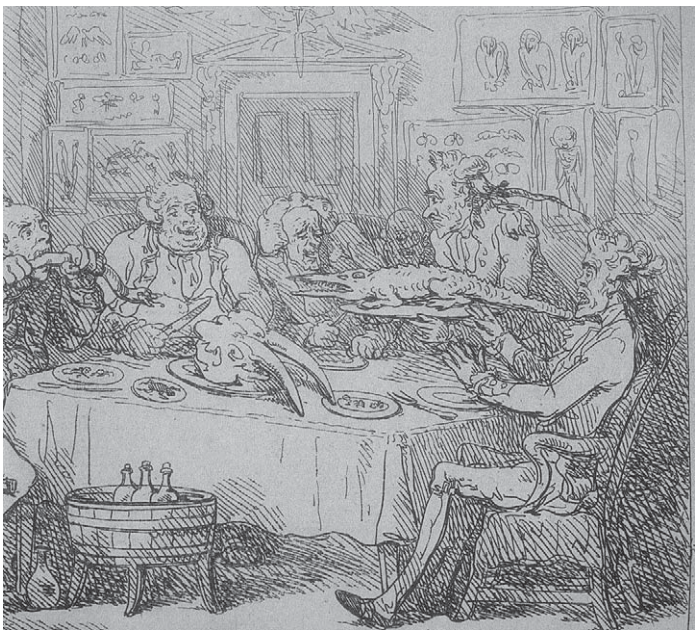
Amphibians and Reptiles of the Southeastern United States

The University of Georgia Press has published four exquisite books on the herpetofauna of the southeastern United States since 2005. The first is *Snakes of the Southeast*, by J. Whitfield Gibbons and Michael E. Dorcas (Athens, Georgia and London, ISBN 13 978-0-8203-2652-8). Three years later, three other books have appeared—*Turtles of the Southeast*, by Kurt. A. Buhlmann, Tracey D. Tuberville, and Whit Gibbons (ISBN 13: 978-0-8203-2904-4; ISBN 10: 0-8203-2902-9); *Amphibians and Reptiles of Georgia*, edited by John B. Jensen, Carlos D. Camp, Whit Gibbons, and Matt J. Elliott (ISBN 10: 0-8203-3111-2; ISBN 13: 978-08203-3111-9); and *Frogs and Toads of the Southeast*, by Michael E. Dorcas and Whit Gibbons (ISBN 13: 978-0-8203-2922-2; ISBN 10: 0-8203-2922-3).

All are of uniformly high-quality, clearly written, with an attractive layout. Each has solid introductory information, detailed species descriptions, excellent range maps and color photographs, line drawings showing defining features, and a strong conservation message. There is an explanation as to how to use the species accounts which will be of value to the lay reader. Several of the books also use "Did You Know?" sidebars to briefly explain interesting facts. One feature, used in the turtle and snake books, is the use of an illustrated sidebar for each taxon to help the non-herpetologist identify an unknown reptile.

Whit Gibbons, now retired Professor of Ecology at the University of Georgia (since 1989) and Senior Research Ecologist, Savannah River Ecology Lab, has written three other books: *Their Blood Runs Cold: Adventures with Reptiles and Amphibians* (ISBN 0-8173-0133-X, University, Alabama: University of Alabama Press, 1983), *Keeping All the Pieces: Perspectives on Natural History and the Environment* (ISBN 1-56098-224-1, Washington, DC: Smithsonian Institution Press, 1993), and *Ecoviews. Snakes, Snails, and Environmental Tales* (ISBN 0-8173-0919-5, University, Alabama: University of Alabama Press, 1998). These books are for a broad audience.

Bon Appétit



Imagine this scenario. You invite that very special someone to your home for a romantic, candlelit dinner. To prepare for the occasion, you pull out your best china, linen, crystal, and silver. When your guest arrives, the lights are turned down and soft music plays in the background. A lovely bottle of wine is opened. After a pleasant interlude of stimulating conversation, dinner is served. You bring the entree in a silver serving dish, remove the cover and plop a Deep Fried Brandied Amphiuma on your guest's plate. Could anyone imagine a more pleasant evening!

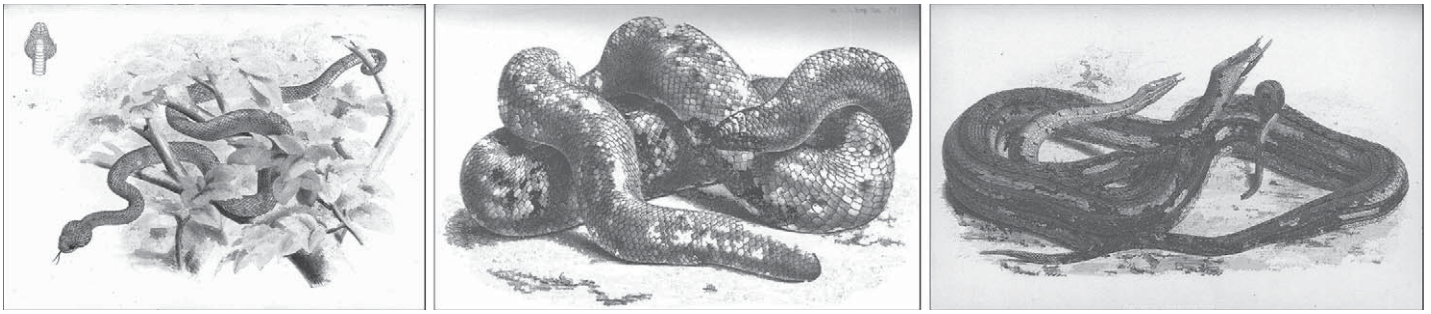
Even if this approach does not appeal to you, you must have *The Culinary Herpetologist* (2005, Bibliomania: Salt Lake City, Utah; ISBN 1-932871-05-5 [hardbound]; ISBN 1-932871-06-3 [paper]), by Ernest A. Liner. The book features over 950 recipes using amphibians and reptiles, though Liner does not recommend exploiting these for food. Rather, he stresses that these recipes are mostly listed for historical purposes.

I have enjoyed Ernie's cooking on several occasions. One of the most memorable followed the SSAR meeting in New Orleans in 1990 where dozens of guests were invited to a Cajun cookout. A huge grill on wheels was rolled into his front yard where roasted meats were prepared. Libations flowed freely and a merry time was had by all. Mercifully, as far as I know, Roasted Poison Dart Frog (Campa Indian Style) was not served.

The Bartlett Society

Abraham Dee Bartlett (1812–1897) was the great nineteenth century Superintendent of the Zoological Society of London from 1859–1897. Two of his books mention herps: *Wild Animals in Captivity Being an Account of the Habits, Food, Management and Treatment of the Beasts and Birds at the 'Zoo'*. . . (1899) and *Bartlett's Life Among Wild Beasts at the 'Zoo'* . . . (1900). The first book covered the habits of tortoises, including a charming story about a museum curator, alone at night when a loud commotion was heard. One of the tortoises, varnished and properly labeled, revived and knocked the other preserved chelonians all over the museum.

Banquet scene from Peter Pindar's *PETER'S PROPHECY … or, An important epistle to Sir J. Banks, on the approaching election of a president of the Royal Society. With an etching by an eminent artist. Third edition. London: printed for G. Kearsley, 1788*. Reproduced from *Slithy Toves: Illustrated Classic Herpetological Books at the University of Kansas in Pictures and Conversations*, by Sally Haines.



Imprint: [Ithaca, New York]: Society for the Study of Amphibians and Reptiles, in cooperation with the Kenneth Spencer Research Library at the University of Kansas, 2000.

In honor of his name, the Bartlett Society was formed for individuals who have an interest in the history of zoos, aquariums, and wild animal husbandry. Clinton Keeling and others founded the Bartlett Society in England on 27 October 1984 (the birthday anniversary of A. D. Bartlett). Soon after this an independent but corresponding branch was formed in North America, covering the United States and Canada.

The Bartlett Society in Britain, which accepts international members,

Force-feeding python at Central Park Zoo in New York. Credit: undated postcard, possibly around 1913, provided by Brint Spencer.

Sampling of snake art from the *Proceedings of the Zoological Society of London* between 1858–1863 (left to right): African Bush Viper (*Atheris burtonii*, now *A. squamigera*); African Burrowing Python (*Calabaria fusca*, now *C. reinhardtii*); Tentacled Snake (*Herpeton tentaculatum*, now *Erpeton tentaculatum*). Credit: collections of the Smithsonian Institution libraries, Washington, D.C.

produces bi-monthly newsletters, annual journals, and occasional special publications, as well as maintaining a zoo history website and holding meetings. There is an annual membership subscription and conditions for membership apply.

The North American branch publishes its own newsletter, and there is no subscription fee, although they do not hold meetings or produce additional publications.

For those interested in zoo history there is also the unrelated Indian organization—The Society for Promotion of History of Zoos and Natural History in India and Asia.

For more information about the Bartlett Society—admin@zoohistory.co.uk or http://zoohistory.co.uk or write to Paul D. Murphy, 81 St James Avenue, Upton, Chester, CH2 1NN. UK.

The founder of the Bartlett Society, the late Clinton Harry Keeling, published many books on British zoos, menageries, aquariums, and wild animal collecting: *Year of Janus* 2000*; Where the Leopard Lazed* 1999; *Where the Macaw Preened* 1993; *Where the Penguin Plunged* 1995; *Wonderful Year* 1995; *Chessington Story: The Story of the Chessington Zoological Garden* 1996; *One Man and His Animals* 1994; *Little Acorns Grow: The Early History of the Linton Zoological Garden . . .* 2003; *Where the Elephant Walked* 1991; *Where the Peacock Screamed. . .* 2002; *Sir Peter's Way: An Account of the Crucial First Year of Whipsnade. . .* 1999; *Where the Zebu Grazed: A Further Study and Discussion on Forgotten Animal. . .* 1989; *Where the Crane Danced: More about Zoological Gardens of the Past* 1985; *and Where the Lion Trod: A Study of Forgotten Zoological Gardens 1984.* Several are particularly relevant to herpetology: *A Short History of British Reptile Keeping* 1992; *Here, There and Regent's Park* 1992; *The Life and Death of Belle Vue* 1987; *Remember Belle Vue* 1997; *Belle Vue Bygones: A Farewell to the Manchester Zoological Garden* 1990; and *They All Came Into the Ark: A Record of the Zoological Society of London in . . .* 1988. All were privately published by Keeling (Clam Publications, Guilford, England).

The Zoological Society of London (ZSL) developed four important serials. The *Proceedings of the Zoological Society of London*, begun in 1833 and later changed to *Journal of Zoology, Series A*, was the vehicle for publishing scientific papers, many in herpetology. The *Transactions* were absorbed into *Journal of Zoology, Series B*. In 1987, *Series A* and *Series B* were merged to form *Journal of Zoology*.

The annual *International Zoo Yearbook*, launched in 1960, is the premier publication for research by zoo and aquarium personnel worldwide. In 1864 the first volume of *The Record of Zoological Literature* was edited by Albert C. L. G. Günther and this series remains a valuable bibliographic reference over 140 years later. The ZSL Symposia series was started in 1960 and many of the volumes are devoted to topics of interest to zoo professionals: captive and medical management, conservation, and other relevant issues.

Art was an important component in the *Transactions* and *Proceedings* of the ZSL, detailed in two excellent books—*Transactions of the Zoological Society of London: An Index to the Artists, 1835–1936*, compiled by Nina J. Root and Bryan R. Johnson. New York: Garland Publishing, 1986; and *Proceedings of the Zoological Society of London: An Index to the Artists, 1848–1900*, compiled by Nina J. Root and Bryan R. Johnson. New York: Garland Publishing, 1986.

Acknowledgments.—I am grateful to Emily Becker, Dana Fisher, and James Hanken from the Museum of Comparative Zoology, Harvard University, for providing most of the illustrations. All colored originals have been converted to a black-and-white format. Thanks are also due to Kraig Adler, Danté Fenolio, Marla Krauss, Polly Lasker, Paul Murphy, Robert Olley, Leslie Overstreet, Jennifer Pramuk, Brint Spencer, and Daria Wingreen. My wife Judith Block read early drafts and made critical changes to make my articles comprehensible.

Part III will appear in the next issue.

—James B. Murphy, Section Editor

Hanzaki Pilgrimage: A Visit to the Home of the Giant Amphibian

KEN KAWATA
23 Arielle Lane, Staten Island, New York 10314, USA
e-mail: Buteo007@aol.com

The Japanese Giant Salamander, *Andrias japonicus*, is a huge aquatic salamander that occurs on southwestern Honshu Island and two southern islands—Shikoku and Kyushu. The species is commonly known in Japanese as "hanzaki" or "hanzake," literally "cut in half," in reference to a false belief that it is able to regenerate itself even if cut in half (Goris et al. 2004). Studies on this indigenous amphibian by Japanese scientists began in 1887 with an account by Prof. Chujiro Sasaki (Kobara 1985; Kuwabara 2007). Captive breeding was first recorded in the Amsterdam Aquarium in 1903 (van Bruggen 2003). More recently, groups of researchers left the familiar zoo and aquarium boundaries for field research. Dr. Jiro Kobara of Asa Zoo, Hiroshima (opened in 1971) was the first of these workers; by 1973 their work was well under way. In 1975, Takeyoshi Tochimoto, Director of Himeji City Aquarium, began fieldwork (Kawata 2006; Murphy 2007). Based on data from the field, Asa Zoo formulated a captive breeding program, and larvae hatched in 1979 (Kuwabara et al. 1989), more than three-fourths of a century after Amsterdam's first breeding.

Hanzaki is protected by Japanese national law. In 1951 the species as a whole (with no specific geographical distributions, as in many other protected species) was designated as a Natural Monument by the Japanese government. In the following year it was upgraded to Special Natural Monument (SNM) status, which placed hanzaki under stricter protective measures. Interestingly, the government agency in charge is the Agency for Cultural Affairs, not the Ministry of the Environment, as one would expect. Thus, in theory the species is regarded as a cultural heritage, rather than a part of nature. The SNM designation adds charisma and potential political clout to the presence of the species. For instance, under the provision of the law a research project that could alter the existing conditions (physical manipulations, capture, transport or invasive surgical procedures) requires a special permit issued by the Agency for Cultural Affairs.

In practice, the process of permit issuance is handled by the board of education of a prefecture. (Japan is divided into four dozen or so administrative and political units called prefectures, similar to provinces or states.) Because of the perceived aura attached to the SNM status, bureaucrats in the prefectural governments within the range of hanzaki tend to guard hanzaki as *their* heritage. This could easily lead to increased political and territorial control. As a result, every step of permit application and implementation requires jumping through hoops, which handicaps researchers. Moreover, there is hardly any communication among prefectural officials. There existed an urgent need for those involved in hanzaki conservation to meet in person. Mr. Tochimoto organized a national annual conference, Asa Zoo staff assisted in administrative aspects, and the first conference was held in 2004. Fifty enthusiasts and experts gathered, an attendance figure which exceeded expectations, to open a communication channel. The attendance grew to 90 for the second conference, and for the third meeting, 150 assembled for technical sessions on a variety of topics. The fourth conference in 2007 was attended by about 100 delegates. With growing interest and concern over the threats to *in situ* populations, hanzaki continues to carry a larger-than-life image, which I was about to explore.

In April 2008, I made a trip to western Japan, into the range prefectures of hanzaki. The trip was prompted by an invitation to a college class reunion, and as a retired zoo man I took this opportunity to visit zoological collections. Also, a part of the itinerary was set aside for paying tribute to those who are associated with the study of this legendary animal. On 6 and 7 April the pilgrimage began at Asa Zoo in Hiroshima. In the science museum of the zoo was a huge preserved specimen, 150.5 cm long and weighing 27.6 kg at the time of its death on 14 July 2002 (it had been maintained elsewhere in Hiroshima Prefecture). There were leaflets and flyers about hanzaki for children, and live specimens, including adults and larvae, were on exhibit at the zoo. I also visited the off-premises breeding area (Fig. 1). It is here that the four-chamber breeding tank was built, designed after the breeding dens in the wild. In 2007, full second-generation hanzaki in captivity were born, three decades after the beginning of the zoo's field study.

After the zoo visit it was time to leave the bustling city, and early on 9 April, Dr. Kuwabara of Asa Zoo picked me up. As he drove through country roads, we reached a pastoral area that can best be described as *satoyama*: for centuries, the center of

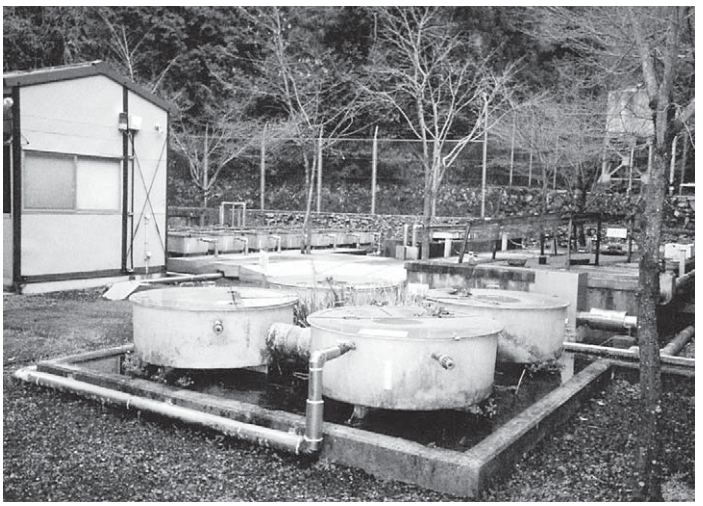

FIG. 1. Off-exhibit hanzaki propagation area, with breeding tanks, Asa Zoo, Hiroshima.

Japan's rural life was represented by an environment consisting of a paddy system (often terraced), streams, ponds, and woods, interconnected with a village where rice farmers lived. This is called *satoyama*, a stable habitat for many wildlife species. (Recently, *satoyama* has been vanishing at a rapid pace due to development.) The car pulled up behind a gasoline station and Kuwabara said, "This is it, the habitat, our study site." I got out of the car. There was nothing exotic or special about this piece of the land for wet cultivation of rice. A stream named Matsuzaigawa flows through paddies and bamboo bushes along houses and a country highway (Fig. 2). But a large sign by the stream, with a cartoon-like hanzaki, clearly states, "Where culture and nature richly intermingle: Forest and river in which hanzaki babies grow." Abruptly, a long-held romantic myth from childhood crashed into flame. For decades, written accounts have convinced us that hanzaki, a mysterious monster, lives in pure streams high up in remote mountains. In reality the pure stream water makes a poor habitat, and hanzaki often live side by side with rural people,

FIG. 2. On the surface it appears to be a typical Japanese pastoral scene; it also represents a hanzaki habitat and the Asa Zoo study site, in Hiroshima Prefecture. A stream (Matsuzaigawa), 1–2 m wide, flows through rice paddies; under the shed lies an artificial breeding den.

as well as in remote mountainous areas.

We met with Mr. Fukunaga, the local representative of the hanzaki program. We then walked across the highway. Before arriving at a Buddhist temple we passed a bridge over a stream which included a hanzaki breeding den. Mrs. Asaeda, the monk's wife, and their daughter greeted us; Mrs. Asaeda was the director of a kindergarden on the temple grounds. The kindergarden was not in session but we walked in, and noticed cloth models of hanzaki, more educational material, newsletters, and other publications. The curriculum centered on hanzaki, and special events are held to celebrate the life of hanzaki. The word "conservation" was largely absent, yet the educational approach no doubt leaves a strong impression on the children's minds. It is essential that local citizens participate in the wildlife research and conservation effort, and a grassroots environmental movement is evident in this small rural community. The villagers have been a vital part of the zoo's research team. For example, the egg-laying season constitutes the most crucial period for researchers, during which they conduct a minute-by-minute, around the clock observation. The temple offers lodging for biologists, who take six-hour shifts for a week to 10 days.

The community participation has its roots in the culture and history of the region. In some parts of Japan, hanzaki is regarded as a delicacy and still is being poached, but that is not the case here. Hanzaki has long been regarded as the mythical master of the river. The zoo group introduced the study of biology and a new meaning for the species to this traditional view. Villagers take pride in their heritage, as noted in the curriculum of the kindergarden. That also explained why the community leaders welcomed this expatriate, who came from New York to see the study site. The community-based effort, however, represents an exceptionally bright spot; hanzaki is lucky to have influential allies in the form of community leaders on its side. After the temple visit we were back to the stream, a habitat that had already gone through a major alteration. Even this serene *satoyama* could not dodge the marching force named progress.

Whatever a visitor sees in Japan could be peculiarly deceiving. The maximum protection by law does not interfere with the devastating act of habitat destruction, which jeopardizes the very survival of hanzaki. Herein lies the ultimate irony concerning the protection of wild hanzaki populations. The construction of weirs and dams, the so-called "reinforcement" of river banks and bottoms with concrete, and the alteration of rivercourses prevent migration, access to nest sites, and limit food supply. The altering of the environment has increasingly fragmented hanzaki's suitable habitats. The relentless destruction of Japan's natural environments, little known to the West, has been chronicled eloquently by Kerr (2001). Should the current course continue, "The future of these magnificent animals, which may be the largest living amphibians, still remains bleak (Goris et al. 2004)." In fact a fleet of bulldozers descended upon the zoo's study site for a project to restructure paddies for mechanized farming. By the time a plan was underway in 1984, the zoo staff had accumulated enough data as a conservation tool.

The stream (Matsuzaigawa) had a population density of 50 hanzaki/km. The stream gradient was about 4 m for a 290-m segment that required, according to the plan, 12 weirs. At this juncture the zoo staff made four recommendations to the civil engineers: 1) avoid straight lines when altering the water course, because floods will push hanzaki downstream; 2) banks may be concreted, but leave the bottom as natural as possible; 3) weirs must have ladders with footholds, properly spaced out to enable climbing by the animals; and 4) build artificial dens. All recommendations were incorporated and the work was completed in March 1985 with the first artificial dens in Japan (Fig. 3). In September of the same year, egg-laying was noted in an artificial den, thus hanzaki's adaptability to a changing environment came as a pleasant surprise for everyone. Villagers continue to participate in the hanzaki project. They patrol the area to ensure that sand and gravel do not block the entrance and the tube to the artificial den after a flood. Through a narrow footpath between rice paddies I reached an artificial den and stared into dark water, imagining how a den master would defend eggs during the breeding season.

It was time to hit the road again. Already into the afternoon Dr. Kuwabara was moving fast, and I was unaware that we had left Hiroshima into another prefecture, Shimane. Soon, the car slowed and two red-slate-roofed buildings were awaiting us. We stepped in the Hanzake Field Museum (opened in 2000), a richly interpretive facility with an auditorium, exhibit halls with graphics, panel displays, preserved and live animals, and a gift shop (Fig. 4). I purchased picture postcards, and picked up attractive leaflets and an excellent booklet on hanzaki (all in Japanese, as usual). The museum is also keen on natural history of the region, in addition to the giant salamander. There are events such as after-dark observation workshops (giant salamanders are mostly nocturnal). There is even a children's song about the giant amphibian; in a nearby township there are a trail and a building over a stream for observation.

However, wandering through the exhibits and chatting with the staff, I could not shake off a question. For this rural area, the museum and other facilities appeared to be a luxury. Well, almost. The town is so far away from any major city, away from hordes of tourists. It must be costly for them to build and operate such a disproportionately large facility, particularly featuring a

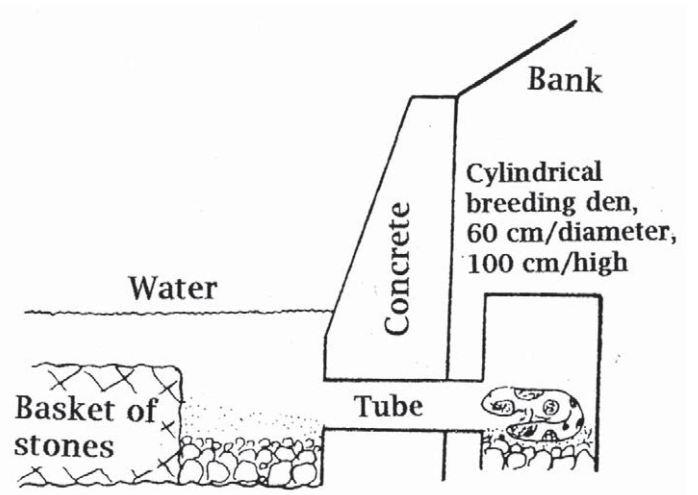

FIG. 3. A cross-section of an artificial breeding den, designed by Asa Zoo staff, patterned after an in situ model. A tube, 15 cm in diameter and 70 cm long, leads to a cylindrical concrete den. Modified after Kuwabara (2004).

FIG. 4. Hanzake Field Museum, Shimane Prefecture.

creature that is not cute and cuddly. The grass-roots enthusiasm must be infectious, but promoting it requires funds and a political will. (Without my asking the question, Ms. Shabana, the museum director, later wrote to me, explaining that the museum was built as a base for an eco-museum concept, and actively being utilized for environmental education.)

As we began our long drive back to Hiroshima, we talked about a new threat to hanzaki. According to IUCN (2008): "It might also be facing competition from the introduced Chinese Giant Salamander (*Andrias davidianus*). Genetic uniformity in this species is high, which increases its vulnerability to threatening processes." A newspaper account noted that Prof. Masafumi Matsui of the University of Kyoto surveyed hanzaki populations in various rivers in 2005 and 2006, and found a large population in Kansai district (west-central Japan). A DNA test revealed that four out of 22 specimens turned out to be *davidianus,* which may have established a breeding population. These four were found in the entrance area of a breeding den during the egg-laying season. The professor commented that *davidianus* could present a serious threat to the conservation of the indigenous *japonicus.* These alien salamanders can be traced back to some 800 *davidianus* that were imported by a dealer in Okayama Prefecture in 1972, and were distributed to restaurants (Anon. 2007). Apparently, the intended culinary delight never caught on, and some of them found their way into local freshwater systems, such as the Kamogawa River in Kyoto.

Also, *A. davidianus* is sporadically found in Japan, after possible release by (or escape from) individuals who imported them. One such example was noted by a Westerner who watched a large specimen in an aquarium in Hakone, Shizuoka Prefecture. "I would have liked to know things like how long it's been at this aquarium and where it came from, but the staff there were few in number and pretty clueless, to say the least. At a couple of other facilities I've seen in Japan, the *A. davidianus* were all 'wild-caught' by fishermen after having been released into local rivers—either having escaped from the menu or having been released after becoming too big and troublesome to be kept in captivity (Johnson 2007)."

From Hiroshima, I headed east and arrived at Hyogo Prefecture, skipping Okayama Prefecture in between. Early in the morning of 12 April, Kakinoki, a young biologist from the Japan Hanzaki Institute, picked me up in front of the train station in Himeji, a city known for the grandest of Japan's remaining feudal castles. After leaving the city, the car started to climb a series of highways into mountainous regions. The higher we climbed, the more desolate the landscape became and soon, a river loomed on the left side of the highway. Up on the steep hillside were tall cedar trees, forming an economically feasible, artificially nurtured forest. What caught my eye, however, was an orange-colored piece of heavy equipment scraping up the riverbed in a repetitive motion (Fig. 5). A layer of vegetation had largely been peeled off of the hillsides, replaced with panels of square concrete frames, possibly for bank reinforcement, as if postage stamp sheets have been slapped upon a naked surface of mucous membrane. This view reminded me of the book by Alex Kerr (2001), which vividly portrays how rivers and streams get violated with emotional impunity. Then the river departed, and our journey to Japan Hanzaki Institute continued. It takes about an hour by car from Himeji, but using public transportation is a different story. It requires a train ride from Himeji, changing trains once, and after one hour one takes a local bus ride for 30 minutes.

After retirement from the directorship of Himeji City Aquarium in April 2005, Takeyoshi Tochimoto established the Japan Hanzaki Institute (Fig. 6). It is located in his study site in this mountainous area, some 470 m above sea level. Surrounded by steep canyons and valleys, this small community typifies a dilemma facing remote agricultural and forestry regions in Japan. Younger generations

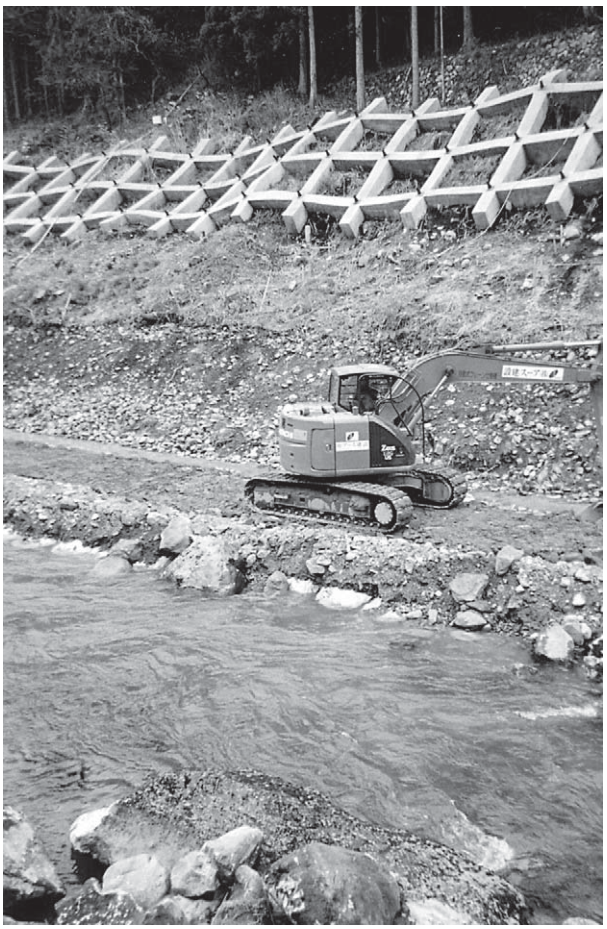

FIG. 5. Rivers and streams are being altered at a rapid pace, a common sight in Japan, Hyogo Prefecture.

FIG. 6. Japan Hanzaki Institute; underneath the bridge flows a river, another hanzaki habitat. Hyogo Prefecture.

depart for cities, leaving behind aging and shrinking populations, cut off from the economic prosperity of urban areas. There was an elementary school that had been closed for over a decade. Located by the river, it consisted of a classroom building, a gymnasium, a principal's residence, and a swimming pool. Mr. Tochimoto rented this facility and converted it into the institute. He gave me a tour of the facility. The images that I had seen earlier in the institute's newsletters began to blend into reality. The classroom building houses a library, lecture rooms, a depository of natural history specimens and artifacts, and his office. The children's swimming pool has become a temporary holding station for hanzaki during river "reinforcement" projects (at my visit he had 60 hanzaki in modified tanks). The foundation is here for the formation of a natural history museum.

Field research is by far the primary mission for the institute. Thus far, 1350 hanzaki have been individually identified in the area. Tagging and recording the pattern of blotches on the tail constituted the initial methods. It became evident, however, that tags fall off, and illustrating the color patterns of so many individuals proved to be an unrealistic approach. Transponders offered a solution, and about 750 animals have been identified by this approach. The long-term goal is to trace their lives in the natural habitat. Hanzaki have a long generation time; sexual maturity takes 16–17 years in captivity. Thus, it might take several generations of researchers to determine the natural life span of hanzaki. Another task for the institute is environmental education. Through classes and other activities, children are taught the importance of hanzaki in their own surroundings. The institute also plans to help to revive the declining village community. By nurturing increased awareness, hanzaki can become the theme for this endeavor and hopefully will attract tourists. At this time the institute is largely a one-man operation, and a step has been taken toward incorporation into a non-profit organization. Currently the institute is open to visitors by advance appointment.

The wholesale destruction of freshwater environments, which has swept the Japanese archipelago, is at work even in this remote region. In a nearby river a flood flushed down a large number of hanzaki below a dam, and 100 of them were seen at the bottom, trying in vain to move back upstream. At the institute I saw a

FIG. 7. Stones chained and strung together, to function as a ladder for aquatic animals from crabs to hanzaki. At the Japan Hanzaki Institute.

photo of one of them with injured feet, as a result of a desperate attempt to climb a concrete wall. More recently, at the urging of biologists, civil engineers and government agents have responded. Mr. Tochimoto showed me some of the remedial measures that construction companies have devised. One was the "shelter block" to be installed on the concreted riverbank. There are various types, but they all have entry holes and cavities for aquatic creatures from invertebrates to fish and hanzaki. Another one resembles a bunch of grapefruits, but instead is made of large stones chained and strung together (Fig. 7). This can be bolted by a weir or dam to enable hanzaki and other creatures such as crabs to climb over.

Mr. Kakinoki's next stop was the site of a large-scale civil engineering project at the Izushigawa River. But we first reviewed commercial trout ponds. During the project hanzaki had to be captured and held, and the civil engineering firm rented rainbow trout ponds for them. At one time Mr. Kakinoki held 400 hanzaki. With the project nearing its end, hanzaki were now being returned to the river. We left the trout ponds for the river, climbed on the riverbank and walked down to stand on top of an artificial hanzaki breeding den. I scanned the panoramic waterscape; it was concreted and reshaped, so far removed from the gentle and embracing image

FIG. 8. Notice the shelter blocks installed (to the left) on the concreted riverbanks. Izushigawa River, Hyogo Prefecture.

of a river. I noted many shelter blocks in use, and Mr. Kakinoki told me that 49% of the 15-km stretch had been treated with shelter blocks (Fig. 8). That constituted quite an effort. It was late in the afternoon, we had to drive back to Himeji and I turned around to take a good look. There is hope, but can hanzaki continue its life cycle in an altered new environment? The jury is still out.

Acknowledgments.—I express my sincere appreciation to Drs. Yukio Fukumoto, Director, and Kazushi Kuwabara, Administrative Director, Asa Zoological Park, and Mr. Takeyoshi Tochimoto, President, Japan Hanzaki Institute, for cordially making arrangements, hosting my visits, and providing literature and information. In two trips, Messrs. Kuwabara and Shunsuke Kakinoki patiently drove through rural areas to introduce me to the animal's habitats, local institutions, and residents. Thanks also go to Dr. Kuwabara for critically reviewing the manuscript.

Essential History of Herpetological Societies: Origins of the ASIH, HL, and SSAR

HARVEY B. LILLYWHITE
Department of Zoology, University of Florida
Gainesville, Florida 32611-8525, USA
e-mail: hbl@zoo.ufl.edu

Recent publication of the new *Dictionary of Herpetology* (Lillywhite 2008) has evoked reassessment of the historical origins of the North American-based herpetological societies: ASIH, HL, and SSAR. Notices about the new book have appeared in emails distributed by the Center for North American Herpetology, and specific references to the entries for these societies in the *Dictionary* require some expanded comments. Here I provide historical details from the published record to clarify the situation.

ASIH

The new *Dictionary* entry for the American Society of Ichthyologists and Herpetologists (ASIH) states that the society was established in 1913 by J. T. Nichols. This is not strictly correct if one refers to the official chronology published by ASIH (Berra 1984). In 1916 a publication committee was established for *Copeia* and consisted of John T. Nichols, Henry Fowler, and Dwight Franklin, who collectively organized the American Society for the Study of Fishes and Reptiles. In the same year bylaws were adopted, and the name of the society was changed to American Society of Ichthyologists and Herpetologists, which held its first official meeting on March 8, 1916 at the American Museum of Natural History. Previously, in December of 1913, John T. Nichols had published the first issue of *Copeia*, named in memory of Edward D. Cope. During these early years the journal was published privately by John T. Nichols. There is no mention of ASIH in the early issues of *Copeia* through 1916.

It is a common confusion that the journal *Copeia* and the society of ASIH began at the same time, but this is not true. However, some herpetologists consider the history of the Society "as one continual event dating back to 1913," and there is little historical information available to judge the definitive history of the Society during its early formative years (Berra 1984). While some may consider the publication of *Copeia* as the rudimentary origin of the ASIH, it seems best to mark the formal birth of the Society as 1916 when the name was officially designated by a duly empowered body.

The Herpetologists' League

With respect to the The Herpetologists' League, the organization's past (but not current) website stated that the HL was established in 1936, as does the entry for "Herpetologists' League" in the new *Dictionary of Herpetology*. To the contrary, this is the year marking the first publication of the journal *Herpetologica*,

founded by C. Grant, W. L. Necker, and H. K. Gloyd. Grant and Necker edited the first issue with the essential support of Gloyd, who was Director of the Chicago Academy of Sciences and allowed Necker to have free access to the printing facilities of the Academy. During these early years the journal was published privately by Chapman Grant. As a society, the HL was started later in 1946 (Smith 1986). There is no mention of The Herpetologists' League in early issues of *Herpetologica* prior to 1946. It is of interest to note that the HL was founded originally as an affiliate of AAAS, and the society met jointly with AAAS for many years until the latter organization terminated meetings with all smaller societies at its annual meetings. As with the ASIH, there is obvious confusion or difference of historical interpretation concerning the origins of the HL being separate from the journal that has been published by that society. Hobart M. Smith (1986) wrote:

> The strangest fact in the history of the Herpetologists' League is that it was born, in 1946, of its journal, *Herpetologica*, established in 1936; the reverse is normal for societies, popular and scientific, and their publications…. A somewhat similar history (Grant, 1947:146) exists in a sister journal, *Copeia*, founded in 1913 by John Treadwell Nichols; the journal was later (1924, No. 126) adopted by the American Society of Ichthyologists and Herpetologists (already in existence for eight years) as its official organ (Dunn, 1924; Nichols, 1923).

As a further complicating historical note, the apostrophe in The Herpetologists' League did not appear anywhere in the League's publications until 1960 (Grant, cited in Smith 1986).

SSAR

There is further misunderstanding concerning the beginnings of SSAR. The new *Dictionary of Herpetology* states the origin of this society as being founded in 1967, but the origins of the SSAR can be traced to 1958 when The Ohio Herpetological Society was founded by Kraig Adler and David M. Dennis (Preest 2007). At the birth of the OHS, the early officers felt a need to form a regional society at a time when the ASIH and HL were already in existence. However, the OHS grew to 75 members and 10 institutions, representing 11 states and four countries, within its first year. In 1967 the OHS changed its name from The Ohio Herpetological Society to the Society for the Study of Amphibians and Reptiles, while retaining the same officers, publications, and constitution. The change of name was made to reflect the increasingly international membership and mission of the Society, which had grown to exceed the regional identity of the organization. Thus, while strict interpretation of the origin of the named society (SSAR) may be problematic to some, OHS and SSAR are one and the same organization, in spite of the name change in 1967. The Society itself regards the SSAR as a "continuation" of the OHS, as recorded in its official silver and golden anniversary publications (Ford and Collins 1983; Moriarty and Bartholomew 2007). Indeed, SSAR celebrated its 50th anniversary meeting last year in Saint Louis, thus recognizing 1958 as its year of founding.

There is an important distinction between the founding of the SSAR and the other two societies. Both *Copeia* and *Herpetologica* were started and run privately by individuals for many years before the two later-associated societies came into being. The OHS, however, began as a society with journal and newsletter from its inception in 1958. What occurred later in 1967 was a mere change of name (to SSAR).

For all three societies discussed here, a few persons have argued for different years, modes of origin, and founders of the organizations and/or with journals that have become the respective central arms of these societies. This statement is important, because I do not wish for the society entries in the 2008 *Dictionary of Herpetology* to be cited as a final authority. It should be up to each society to record its own history. Disagreement will likely continue in spite of the suggestions here favoring the stringent interpretations stated, which are based on the published record.

Acknowledgments.—This communication is published with the approval and support of the Presidents of each of the societies that are discussed: Henry Mushinsky (ASIH), David Cundall (HL), and Roy McDiarmid (SSAR). I am also grateful to Harry Greene, Kraig Adler, and David Cundall for relevant comments and improvements to the manuscript.

Ecology and Natural History Observations of the Salamander, *Siren intermedia nettingi* (Western Lesser Siren), in Northern Indiana

ROBERT BRODMAN
Biology Department, Saint Joseph's College
Rensselaer, Indiana 47978, USA
e-mail: bobb@saintjoe.edu

The Lesser Siren (*Siren intermedia*) is an unusual two-legged salamander with external gills retained into adulthood. They inhabit shallow semi-permanent and permanent wetlands, sloughs and ponds that have abundant aquatic vegetation and deep mucky to sandy sediment that provides burrowing sites (Petranka 1998; Smith and Minton 1957). Lesser Sirens are able to survive droughts by using crayfish burrows or burrowing into mud to depths from 8 cm to 1 m where they aestivate until the pool refills (Blatchley 1900; Cagle 1942; Harding 1997).

The Lesser Siren also has an unusual distribution, inhabiting the Atlantic and Gulf Coastal Plains with a northern extension through the mid-Mississippi, Illinois, and Wabash Vallies (Leja 2005; Petranka 1998). The western subspecies (*S. i. nettingi*) is found in Indiana throughout the Wabash and Kankakee drainages with isolated populations in the Lake Michigan drainage in extreme northwestern Indiana (Atkinson 1896; Minton 2001). The northern populations in Indiana are often fragmented and isolated (Brodman 2003; Brodman and Kilmurry 1998; Leja 2005; Petranka 1998).

Because these amphibians are highly secretive and difficult to observe, relatively few ecological studies have been conducted on Lesser Sirens (Petranka 1998), and, moreover, very few of these studies have been on northern populations. Ecological studies and natural history observations of northern populations of Lesser Sirens should provide useful information for conservation and increase the understanding of the ecology of species distributed along a north-south axis. Herein field and laboratory observations of population trends, body size, diet, habitat preference, and aestivation for Lesser Siren populations in northern Indiana over an eleven-year period are provided.

Methods

Lesser Sirens were sampled from 1998–2008 from 21 sites at Jasper-Pulaski Fish and Wildlife Area in Indiana. These populations are among the most northern extant populations known for this species (Fig. 1). The sites consisted of 11 seasonal to semi-permanent wetlands, two permanent wetlands, five shallow lakes and three drainage ditches. Each site was visited several times a year in May, June, and October after sundown to search for active sirens by flashlight. However the primary method for sampling sirens was using un-baited metal minnow traps in March, April, June, September, October, and November. Minnow traps were placed in shallow areas near aquatic vegetation. The number of traps and the number of days that traps were set varied among sites and among years because ponds dried at different times and could no longer be surveyed. I recorded the number of animals caught per trap-day for each site and year to standardize the data.

All traps were checked within 24 h of being set and all of the animals caught by traps were identified and released. The sirens were measured (TL) and inspected for scars and malformities before being released. Sirens were not sexed or marked. Sirens greater than 18.0 cm in TL were recorded as adults (Petranka 1998). A small number of sirens escaped before being measured and another small number of sirens were found dead in the minnow traps. All of the dead sirens were preserved as vouchers in 70% isopropyl alcohol and deposited in the Saint Joseph's College Zoology collection. Sirens were later dissected to determine stomach contents. Prey items were identified to family using Pennak (2001).

Habitat characteristics of each site (depth, vegetation type, hydroperiod) were recorded. In 2003 samples of the substrate where minnow traps were placed were collected and analyzed to determine soil characteristics and pH.

In 1998 half of the minnow traps were baited with sardines and half were un-baited to determine if bait would increase the number of sirens caught in traps. In 1999 half of the minnow traps were plastic and half were metal to determine if one type was more effective in capturing sirens. In 2004 half of the minnow traps were altered by increasing the opening from 3 to 5 cm to determine

Fig. 1. The distribution of the Lesser Siren (indicated in gray), adapted from Minton (2001) and Lannoo (2005). The black area indicates the location of the study sites at Jasper-Pulaski Fish and Wildlife Area.

if a larger opening would increase the maximum size of sirens captured.

Six adult sirens in fall 1998 and 18 sirens (nine juveniles and nine adults) in fall 2004 were collected from one site and kept in aquaria for observations of behavior and feeding. In 1998 pairs of similar sized sirens were kept in three 56.8-liter glass aquaria filled with 40 liters of un-chlorinated well water over a 3 cm layer of aquarium gravel. The sirens were observed in captivity for four weeks and then released at the site of capture. The sirens were fed a variety of live prey including earthworms, *Tubifex* worms, aquatic insects, crustaceans, snails, clams, tadpoles, fish, and also processed food such as shrimp pellets, mussels, and sardines. Each siren was observed a number of times during the day and after sundown with 1-lux lights covered with red cellophane filters.

In 2004 individual sirens were kept in eighteen 17.9-liter plastic containers measuring 26.5 cm H × 32.5 cm L × 23.5 cm W to study aestivation. A control group (three adults and three juveniles) had a 13 cm layer of sediment from the natural pond and 7.5 liters of pond water added to the container which resulted in a layer of standing water 10.5 cm above the surface of the pond substrate. To prevent aestivation in the control group, pond water was periodically added to these containers to maintain the water level. Two treatment groups were set up to simulate pond drying. The slow drying treatment (three adults and three juveniles) had 4.5 liters of pond water added to the containers resulting in a 7.5 cm layer of standing water over a 13 cm layer of pond substrate. The fast drying treatment (three adults and three juveniles) had 3.0 liters of water added to containers resulting in 6 cm of standing water over a 13 cm layer of pond substrate. The drying treatments were allowed to dry to initiate aestivation of sirens. Until sirens initiated aestivation, they were fed live earthworms and observed daily after sundown with 1-lux lights covered with red cellophane filters. The position of each siren was recorded (water column, on substrate, body inside borrow but with head out, inside burrow with opening unplugged, inside burrow with opening plugged with mud) during each observation. Sirens were considered to be aestivating when they were buried in the substrate with the burrow opening plugged with mud for an extended number of days. The experiment was terminated after four months when aestivating sirens were removed from the dry mud. The presence of a secreted cocoon around an inactive siren was used to confirm aestivation. Aestivating sirens were then re-hydrated with un-chlorinated well water. Surviving sirens were released at the site of capture.

Regression was performed as exploratory analyses to determine if there were any relationships among abundance, TL, size class, diet, substrate (soil type and pH), coexisting species, habitat and recovery from aestivation. ANOVA was used to determine if minnow trap treatments (altered vs. unaltered opening, plastic vs. metal, baited vs. un-baited) affected the number or size of sirens captured. MANOVA was performed to test the effects of drying treatments and age class on siren behavior and survival.

Results

Population trends.—From 1998–2008 a total of 167 sirens were captured in 2633 trap-days. This is a mean of 15.2 sirens captured in 239 trap-days per year. The number of sirens captured per trap-day fluctuated from year to year with spikes in abundance in 1998, 2001, and 2007 followed by declines over the following two years (Fig. 2). There were no significant differences ($\alpha = 0.05$) in the number of sirens captured in baited traps, plastic traps or traps with enlarged openings compared to un-baited, metal, unaltered minnow traps.

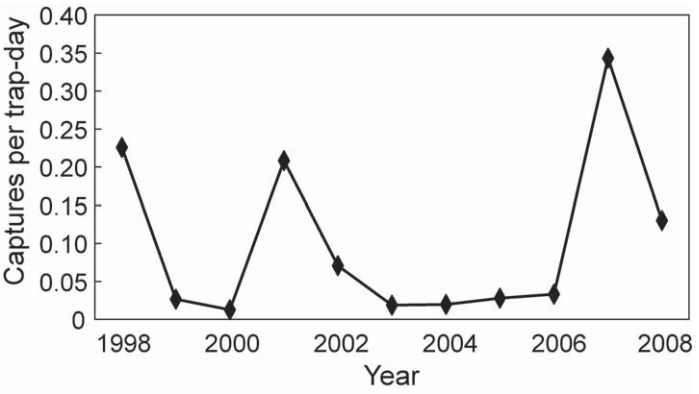

Fig. 2. Population trends of Lesser Sirens at Jasper-Pulaski Fish and Wildlife Area. Values are the number of sirens caught per trap-day of effort from 1998–2005.

The mean and SE of the TL of sirens captured in minnow traps was 26.5 cm ± 1.1 (range 13.0–43.2 cm, N = 118) and has increased significantly over time (Regression; $F_{1,10} = 28.138$, $P < 0.001$, $r = 0.870$). The mean and SE of the TL of adults was 32.3 cm ± 0.9 and the mean and SE of the TL of juveniles was 15.9 cm ± 0.4. Overall 66% of the sirens captured were adults and 34% were juveniles. The proportion of adults to juveniles (Fig. 3) has increased significantly over time (Regression; $F_{1,10} = 10.884$, $P = 0.009$, $r = 0.740$). Adults made up 75% of the sirens captured from 2002–2008 but only 41% of the sirens captured from 1998–2001. There was no significant difference in the TL of sirens captured in altered traps (5 cm openings) compared to unaltered traps (3 cm openings). Sirens captured from a given site in a given year were typically of the same size class.

In addition to sirens, 9779 individuals of other taxa were captured in the minnow traps. These included 249 large aquatic insects (predaceous diving beetles, Dysticidae; dragonfly naiads, Anisoptera; water scorpions, Nepidae; giant water bugs; Belostomatidae), 344

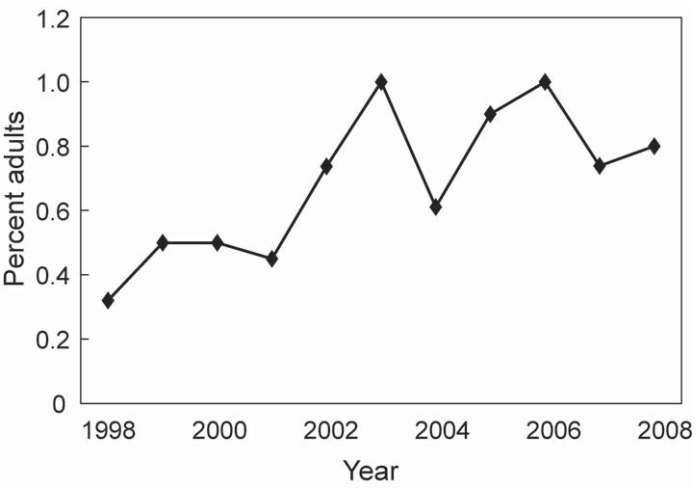

Fig. 3. The percentage of Lesser Sirens caught each year that were adults.

crayfish, five Eastern Newts (*Notophthalmus viridescens*), 5353 larval and adult anurans (Spring Peeper, *Pseudacris crucifer*; Western Chorus Frog, *P. triserata*; Eastern Gray Treefrog, *Hyla versicolor*; American Bullfrog, *Rana catesbeiana*; Green Frog, *R. clamitans*), six snakes (Eastern Ribbon Snake, *Thamnophis sauritus*; Western Fox Snake, *Elaphe vulpina*; Northern Watersnake, *Nerodia sipedon*), and 1028 fish (Central Mudminnow, *Umbra limi*; Black Bullhead, *Ameiurus melas*; Pickerel, *Esox americanus*; Green Sunfish, *Lepomis cyanellus*; Lake Chub, *Couesius plumbeus*; Pugnose Minnow, *Opsopeodus emiliae*). There was a positive relationship between the number of sirens caught and the number of fish and crayfish caught (Regression; $F_{1,21}$ = 13.04, P = 0.002, r = 0.638).

Habitat.—Sirens were found in 6 (28.6%) of the 21 surveyed sites. Three of these sites were shallow lakes, two were semi-permanent wetlands, and one was a drainage ditch. Sirens were not significantly more abundant in lakes and ditches than wetlands (Regression; $F_{1,20}$ = 3.337, P = 0.084, r = 0.387). The lakes and wetlands with siren populations all had more than 50% of the surface area with abundant emergent vegetation and the ditch had more than 50% of its surface area covered with large mats of green algae.

A few of the sirens that were observed by flashlight at night were swimming in the water column, but usually sirens were observed motionless on the substrate with a portion of the tail and body hidden in the vegetation or under an algal mat. When disturbed sirens would either swim into the cover of vegetation or algal mats, or into the substrate under rocks or logs.

The sites with sirens all had very poorly drained, loamy, fine sand substrates with near neutral pH (6.0–7.5) and water with high turbidity while substrates from sites that lacked sirens had silty acidic substrate soils and clear acidic water (5.1–6.0). Siren abundance was significantly greater at sites with higher substrate pH (Regression; $F_{1,5}$ = 10.140, P = 0.033, r = 0.847).

Diet.—Sirens kept in captivity were observed to eat a wide variety of prey. They readily ate live earthworms (Oligochaeta), *Tubifex* worms (Oligochaeta), dragonfly naiads (Odonata: Anisoptera), damselfly naiads (Odonata: Zygoptera), crawling water beetles (Coleoptera: Haliplidae), water boatmen (Hemiptera: Corixidae), isopods (Crustacea: Isopoda), crayfish (Crustacea: Decapoda), spire snails (Lymnaeidae), fingernail clams (Sphaeriidae), tadpoles (*Pseudacris triseriata* and *Rana clamitans*), and Central Mudminnows (*Umbra limi*). Sirens reacted to prey by fanning their heads from side to side to orient and move toward prey in such a way that vision is unlikely to be the primary sense used to find food. They primarily ate smaller prey, such as worms, aquatic insects, spire snails, fingernail clams and isopods, by suction feeding. However for prey that was too large to be swallowed whole, the sirens would kill and eat the prey by taking bites out of it. For example, sirens would bite off the viscera of mudminnows and *R. clamitans* tadpoles or the carapace of crayfish. Some of the adult sirens (TL = 29–33 cm) were able to kill and eat relatively large (TL up to 10 cm) crayfish in this manner. After eating the viscera, sirens would often leave the carcass alone and then scavenge on it the next evening. I also observed sirens scavenging dead fish and mussels and also eating commercial fish food such as shrimp pellets.

Some of the sirens captured in 1998, 1999, and 2001 in deeper water (≥1 m) during hot weather in September died in the trap. Starting in 2002, minnow traps were kept in shallower water with the top of the trap just above the surface when temperatures were higher than 25ºC. I dissected 17 sirens (N = 11 adults, six juveniles; mean TL = 24.7 ± 1.9 cm, range TL 14.0–33.0 cm) that were found dead in minnow traps to analyze stomach contents. A total of 128 prey items of 13 taxa were found in the stomachs and identified (Table 1). All sirens had at least two prey items and as many as 23. Dragonfly naiads were the most abundant prey item (29% of prey items) and found in the most sirens (52%). Four prey taxa (dragonfly naiads, caddisflies, aquatic beetles, and ostracods) made up 75% of the prey items. Dragonflies, aquatic beetles, ostracods, and tadpoles were eaten by the most sirens. Minor constituents of the diet included clams, tadpoles (*Pseudacris* and *Rana*), oligochaetes, chironomid larvae, damselfly naiads, dobsonfly larvae (Megaloptera), crayfish and *Daphnia* (Cladocera). The TL of the sirens significantly affected the diet. Juveniles ate significantly more caddisflies (Regression; $F_{1,16}$ = 4.765, P = 0.045, r = -0.50), ostracods (Regression; $F_{1,16}$ = 6.966, P = 0.019, r = -0.57), and snails (Regression; $F_{1,16}$ = 6.666, P = 0.021, r = -0.56) and significantly fewer tadpoles (Regression; $F_{1,16}$ = 9.571, P = 0.007, r = 0.41) than adults. One juvenile and one adult siren

TABLE 1. The diet of Lesser Sirens from examination of stomach contents (N = 17). Data are the mean number of prey items for each prey taxon per siren, the percentage of sirens that ate each taxa, and the mean number of prey items per juveniles (N = 6) compared to adults (N = 11).

Prey taxa	prey items	% of sirens	juvenile	adult
Dragonfly naiads	2.18	53	2.17	2.18
Caddisfly larvae	1.59	12	4.50	0
Crawling water beetles	1.06	47	1.33	0.91
Ostracods	0.82	29	2.00	0.18
Snails	0.47	18	1.33	0
Clams	0.29	18	0.50	0.18
Tadpoles	0.24	24	0	0.36
Oligochaetes	0.24	18	0.17	0.27
Chironomid larvae	0.24	12	0.50	0.09
Damselfly naiads	0.18	6	0	0.27
Dobsonfly larvae	0.12	6	0.33	0
Cladocerans	0.06	6	0	0.09
Crayfish	0.06	6	0	0.09
Total Prey Items	**7.53**	**100**	**12.83**	**4.63**
Additional stomach contents				
Nematodes	0.76	24	0	1.18
Algae	0.12	12	0.17	0.09

had algae in their stomach and a total of 13 Ascaridida nematodes were found in four of the adult sirens. The nematodes ranged in size from 1.5–1.7 cm in length and unlike other taxa they showed no signs of being digested.

Aestivation.—Sirens that were placed in containers with mud and water were observed to dig burrows into the mud. The sirens were often observed either lying on the substrate or with their heads and forebodies in the water while their hindbodies and tails were in the burrow. Sirens were observed to initiate aestivation when the depth of standing water was 1–5 cm. On day 22 of the experiment the mean depth of water in the slow drying treatment (4.08 ± 0.13 cm) was significantly greater (MANOVA; $F_{1,12} = 23.021$, $P = 0.001$) than the fast drying treatment (1.80 ± 0.20 cm), and half of the sirens in both treatments were buried in the substrate with the opening of the burrow plugged with mud. No sirens in the fast drying treatment were observed out of the substrate after day 22 and no sirens in the slow drying treatment were observed out of the substrate after day 32. After those dates, all of the sirens were buried in the substrate with the burrow openings plugged with mud. On day 36 of the experiment, all of the fast drying treatment containers had no standing water and on day 53 of the experiment, all 12 containers in the drying treatments had no standing water. From day 33 to completion of the experiment on day 120, all 12 sirens in the drying treatments remained burrowed into the substrate. None of the control sirens ever buried themselves with a plugged opening and were observed to be active throughout the experiment. There was a significant effect of age class on the number of days that sirens were active before entering aestivation (MANOVA; $F_{1,17}$, $F = 6.640$, $P = 0.024$). Juveniles (28.33 ± 0.13 days) were active significantly longer than adults (22.83 ± 0.83 days). Drying treatment had no significant effect on the mean number of days that sirens were active.

Drying treatments had a significant effect on the survival of sirens (MANOVA; $F_{2,17} = 6.333$, $P = 0.013$). All six control sirens survived throughout the experiment. All six sirens in the slow drying treatment had secreted cocoons surrounding the animal. However, one juvenile and one adult were found dead. Only two sirens, one adult and one juvenile, survived the fast drying treatment. Most of the dead sirens were desiccated but each had a secreted cocoon layer indicating that they went into aestivation before dying. One of the dead adults in the fast drying treatment was in similar body condition to the sirens that survived but it did not revive after 24 h of re-hydration. All of the surviving sirens became active within an hour after being re-hydrated.

Discussion

This is the first report of population trends of the Lesser Siren. Populations fluctuated over an eight-year period with two peaks in abundance followed by two declines. Siren density is likely to be high during the peak abundance years. Mean density can be as high as 1.3 sirens/m^2 (Gehlbach and Kennedy 1978). The abundance of Lesser Sirens was positively associated with the abundance of crayfish and fish.

It has been concluded that it is difficult to determine adundance of sirens because of their secretive nature and difficulty catching them with dip nets (Leja 2005; Petranka 1998). However, other observations that Lesser Sirens are easily caught at various times of the year by un-baited minnow traps (Gehlbach and Kennedy 1978; Gibbons and Semlitsch 1991; Raymond 1991; Sever et al. 1996) were confirmed. For the sites in which sirens were present, they were captured at a mean rate of about 1 siren per 12 trap-days.

The range of TL of adult sirens in this study fits the range of 18–50 cm for other populations (Petranka 1998). However during the first year of the study most sirens captured were juveniles and small adults that were similar in size to Indiana specimens reported by Minton (2001). Minton (2001) found that the mean TL of 13 adult Lesser Sirens from Indiana was 23.1 cm with a range of 18.3–28.4 cm. It is possible that northern populations are a smaller race. However Smith (1961) found that there were no trends in geographic variation in TL of specimens captured in four regions of Illinois, and larger sirens were observed after the first year of this study in northwest Indiana.

Samples from other populations show aggregations of 2–4 size classes within a population (Cagle and Smith 1939; Gehlbach and Kennedy 1978; Petranka 1998). Samples in this study best fit two size classes (juveniles 13–18 cm and adults 23–43 cm) with a small percentage (< 6%) of individuals intermediate (19–22 cm) between these size classes. Often, nearly all of the individuals from a specific site in a specific season were from the same size class. It is possible that same-aged cohorts aggregate in a habitat resulting in fluctuations from year to year in TL and juvenile to adult ratio at a particular sampling site.

In this study sirens were found to be more abundant in habitats with soft sandy loam bottoms and in habitats with abundant emergent vegetation and leaf litter. Juveniles live in burrows or in thick mats of aquatic vegetation (Petranka 1998) and adult sirens hide in individual retreats in burrows, beneath logs or in thick vegetation (Asquith and Altig 1987; Bennett and Taylor 1968; Davis and Knapp 1953). The habitats in this study where sirens were abundant would allow for burrowing into soft substrates and refuge in thick vegetation. Sirens were observed to forage on pond bottoms at night, often with the tail end of the body hidden in vegetation or leaf litter as has been reported elsewhere (Fauth et al. 1990; Minton 2001; Noble and Marshall 1932). All of the sites with sirens present were either semi-permanent or permanent bodies of water that held water for at least six months of the year. Sirens have never been seen or captured in any of the many temporary and seasonal wetlands at Jasper-Pulaski that have been observed to dry for more than six months of the year (Brodman 2003; this study). These observations support the hypothesis that Lesser Sirens are restricted to wetlands that hold water at least six months a year (Snodgrass et al. 1999). Southern populations of Lesser Sirens have been associated with acidic conditions (Carr 1940; McAllister et al. 1994). However, the northern populations in this study were associated near neutral pH and were absent from sites where the pH was below 6.0.

There has been some disagreement over whether Lesser Sirens feed on small fish (Altig 1967; Davis and Knapp 1953; Hurter 1911; Pope 1964; Scroggin and Davis 1956). It has been hypothesized that Lesser Sirens feed by filter feeding through bottom material or within the burrow (Altig 1967; Reilly and Altig 1996) and are not capable of catching larger or more mobile prey (Davis and Knapp 1953). Stomach contents from the study population indicate that Lesser Sirens primarily eat small benthic aquatic invertebrates but also eat larger more mobile prey such as tadpoles. Captive Lesser

Sirens were observed to use suction feeding when foraging on small prey, but adults also predated and scavenged prey that was too large to swallow whole, such as mudminnows, tadpoles, and crayfish.

Juveniles have been reported to feed mostly on zooplankton and small macroinvertebrate prey such as amphipods, craneflies and lumbriculid worms (Carr 1940). In this study juveniles ate more ostracods, caddisflies, and spire snails than adults while adults were more likely to eat tadpoles than juveniles. Adults have been reported to eat a wide variety of small aquatic invertebrates such as crustaceans, insect larvae, snails, clams as well as some larger prey such as crayfish, tadpoles, and salamander larvae (Davis and Knapp 1967; Fauth 1999; Fauth and Resetarits 1991; Fauth et al. 1990; Scroggin and Davis 1956). Cladocerans, ostracods, snails, sphaeriid clams, and mayflies have been reported to be the most important prey, often making up more than 80% of the diet (Altig 1967; Davis and Knapp 1953; Scroggin and Davis 1956). Dragonflies, caddisflies, crawling water beetles, ostracods, spire snails, sphaeriid clams, and aquatic oligochaetes were the most important prey items in the diet of the study population. These observations and reports confirm that Lesser Sirens eat a wide variety of prey and the diet is likely dependent on prey availability in the habitat.

Nematode parasites, including intestinal parasites in the order Ascaridida, have been documented in Lesser Sirens (Dyer 1973; McAllister and McDaniel 1992; McAllister et al. 1994). Ascaridida were found in about a quarter of the dead specimens examined in this study. Ascaridida are hypothesized to infect sirens from ingestion of minnows (McAllister and McDaniel 1992). Observation of sirens preying upon mudminnows in the lab and the fact that nematodes were only present in the digestive tract of adult sirens that are large enough to eat small fish make this hypothesis plausible.

Filamentous algae have been documented from dietary studies of Lesser Sirens (Bennett and Taylor 1968; Davis and Knapp 1953; Noble and Marshall 1932; Scroggin and Davis 1956) and were confirmed in some specimens in this study. Algae and plant debris pass through the gut undigested and are likely to be accidentally swallowed along with prey while foraging among vegetation (Davis and Knapp 1953; Petranka 1998).

When the habitat dries, Lesser Sirens retreat to depths of 0.45–1 m into crayfish burrows (Cagle 1942; Pope 1964) or burrow into mud to aestivate (Harding 1997). It has been hypothesized that the western edge of the range of Lesser Sirens is limited by dry conditions (Gehlbach et al. 1973). Under laboratory conditions juvenile and adult Lesser Sirens were able to aestivate in a shallow (13 cm) layer of pond substrate and survive for 2–3 months. However survivorship was dependent upon the drying regime. Aestivation can last from several weeks to > 1 year (Gehlbach et al. 1973). In Indiana, Lesser Sirens were found aestivating at a depth of 8–10 cm in the dry mud of a pond bottom that had been dry for 8 months (Blatchley 1900). In the lab, small sirens are reported to starve 12–14 weeks after initiating aestivation, but large sirens survive at least 16 weeks (Gehlbach et al. 1973; Petranka 1998). Adults initiated aestivation sooner than juveniles. However there was no difference in mortality between size classes over a 12–14 week period of aestivation.

Loss of habitat and habitat fragmentation are threats to Lesser Siren populations (Bury et al. 1980; Petranka 1998). They are possibly extirpated from the Great Lakes drainage basin because of habitat loss and rotenone treatment (Harding 1997). Loss of extensive wet prairie in Illinois and Indiana (Brodman and Kilmurry 1998; Prince 1997) has likely reduced siren populations in the lower Midwest (Leja 2005). Ecology and natural history information will be needed for the conservation of threatened Lesser Siren populations. Future studies need to be conducted on dispersal and colonization to understand how habitat fragmentation and the geographic isolation of northern populations affect the long-term survival of this species in the lower Midwest.

Acknowledgments.—I thank T. Kretz, C. Martin, D. Koleszar, R. Hoffman, M. Parrish, T. Sasak, R. Dorton, S. Finerty, D. Ritchie, T. Farkaly, E. Gall, D. Williams, C. McGann, S. Martin, P. Seth, M. McGuiggan, S. Osterfeld, N. Lenzo, B. Flanagan, and C. Crum for assistance in the field. I also thank T. Kretz for performing soil analyses and J. Askwith for reviewing the manuscript. I also thank the Indiana Department of Natural Resources for permission to work at Jasper-Pulaski Fish and Wildlife Area and to collect sirens. This study followed Saint Joseph's College guidelines for animal care protocols.

A Data Aggregation Problem in Studies of Upper Respiratory Tract Disease of the Gopher Tortoise

Conservation efforts could be improved markedly by involving health professionals (e.g., Deem et al. 2001; Kock 1996) and, conversely, disease control efforts could be improved markedly by involving ecologists (e.g., Kazura and Bockarie 2003; Wasserburg et al. 2002). The role of ecologists in dealing with disease threats to wildlife is destined to grow, in response to increasing recognition that local (e.g., Ross 2002) and global (e.g., Chan et al. 1999) environments influence disease transmission and prevalence, and, in turn, that environmental improvement can mitigate the consequences of disease (e.g., Woodroffe 1999). As ecologists become more involved in studying disease threats and other risks to individuals, they are likely to encounter data aggregation problems that, although familiar to researchers in a wide variety of other disciplines, seem not to be familiar to many ecologists. Ecologists must become more aware that these serious, but difficult to recognize, problems can arise any time one infers individual attributes from population-level attributes. I present a detailed illustration of one such data aggregation problem, involving studies of upper respiratory tract disease (URTD), an emergent disease of turtles.

Emergent diseases are those whose incidences have increased within the past two decades or threaten to increase in the near future (Lederberg et al. 1992), and they are recognized in wildlife, as well as in humans and domesticated animals (Daszak et al. 2000; Williams et al. 2002). The principal causal agent of URTD is the bacterium *Mycoplasma agassizii* (Baseman and Tully 1997; Brown et al. 1994; McLaughlin 1997; Schumacher et al. 1993). *Mycoplasma agassizii* was unknown until the early 1990's, when it was recorded from the Desert Tortoise, *Gopherus agassizii*, in the southwestern U.S. (Jacobson et al. 1991, 1995), and from the Gopher Tortoise, *G. polyphemus*, in the southeastern U.S. (Beyer 1993), but URTD has become a major concern for researchers studying North American tortoises. *Mycoplasma agassizii* is easily transmitted by direct contact between individuals (Brown et al. 2002; McLaughlin 1997), and URTD is potentially lethal (e.g., Berry 1997; Jacobson et al. 1991; Seigel et al. 2003 and references therein). *Gopherus polyphemus* researchers have speculated that URTD may not affect individuals of all sizes equally, because of size-specific differences in encounter rates, which, in turn, result in size-specific differences in the probability of infection or re-infection with *M. agassizii*.

A study by Seigel et al. (2003) addressed the question of whether the risk of death from upper respiratory tract disease (URTD) is related to body size. The study compared the mean size of individuals found dead, as a direct or indirect consequence of URTD, to the mean size of live individuals in the same population. The authors concluded that the mean sizes of dead and live individuals could not be distinguished for either sex,

TABLE 1. Mean sizes (carapace length) of live (two studies) and dead (four studies) individuals of the Gopher Tortoise, and one-way ANOVA comparisons of the mean sizes of live and dead individuals.

	LIVE (mm)	DEAD (mm)	F	df	P
Seigel et al. (2003)*					
Females	263 ± 28.6 (N = 51)	261 ± 35.3 (N = 9)	0.05	1, 58	0.82

Males	—	240 ± 15.1 (N = 25)			
Gates et al. (2002)					
Females	—	262 ± 19.7 (N = 16)			
Males	—	246 ± 20.6 (N = 39)			

* Used plastron length as the measure of size, which, when plotted against carapace length, displays a slope close to 1 for the individuals in a population.

although "live males were somewhat larger than males found dead, and the difference bordered on statistical significance" (Table 1). I compared the mean size of individuals found dead to the mean size of live individuals at a site where intact shells of dead individuals were found during transect surveys (McCoy et al. 2006, 2007). The mean size of dead males could not be distinguished from the mean size of live males, but the mean size of dead females was smaller than the mean size of live females (Table 1).

The fact that similarly designed studies reached different conclusions will not surprise many ecologists: they would likely attribute the difference simply to natural variation. However, careful examination of the experimental design employed in these studies suggests another possible reason for the difference. The question of interest is whether risk of death per individual is independent of body size. Because direct information on individual risk is not available, the size distribution of dead individuals is used as surrogate data. The test then applied to the surrogate data is a comparison of the mean size of dead individuals to the mean size of live individuals. This experimental design requires, therefore, that both the risk of death per individual and any difference in mean sizes of dead and live individuals have the same cause, namely URTD. The difference in mean sizes of dead and live individuals depends on the size distribution of live individuals in a population, however, which varies among populations for reasons that could have little or nothing to do with URTD, such as differences in individual growth rates (Mushinsky et al. 1994). If the experimental design is inappropriate for the reason I have suggested, then these two studies have not addressed the question of interest.

Comparison of the data (Table 1) strongly suggests that the two studies indeed are not addressing the question of interest. The mean sizes of dead males were similar between studies (244 and 246 mm), as expected if URTD actually was targeting individuals by size. At our study site, more shells of dead individuals than expected from the size distribution of live individuals were intermediate in size (156–263 mm; $\chi^2 = 8.67$, $P < 0.01$). The mean sizes of dead males in two other studies that reported only sizes of dead individuals (Table 1) also were < 246 mm. So, there is reason to suspect that relatively small males are affected more severely by URTD. The difference between the mean sizes of dead and live was insignificant for the population with the mean size of live males (248 mm) more similar to that of dead males (McCoy et al., unpubl. data), but "bordered on statistical significance" for the population with the mean size of live males (259 mm) less similar to that of dead males (Seigel et al. 2003). In other words, the size distributions of live males are driving the conclusions, and obscuring whatever connection between body size and URTD that may exist. For females, the mean sizes of live individuals are similar between studies (263 and 265 mm), but the mean sizes of dead individuals are not as similar (261 and 244 mm). Consequently, the conclusions depend on the nature of the size distributions of dead individuals: comparison of the means sizes of dead and live females indicated a significant difference for the population with a relatively small mean size of dead individuals (McCoy et al., unpubl. data), but not for the population with a relatively large mean size of dead individuals (Seigel et al. 2003). Perhaps no size-specific effects of URTD exist for females; perhaps URTD affects females differently than males; perhaps the larger mean sizes of dead females (261 and 262 mm) in two of the four studies may be a simple consequence of the populations and/or sexes being in different phases of the progression of the disease. The available data do not offer any insight into these possibilities.

Data aggregation problems may occur whenever population-level attributes, such as size distributions, influence assessment of individual attributes, such as risk of death. These problems apparently are not commonly recognized in ecology (but see Levins and Lewontin 1985), although they are well recognized in a variety of other disciplines (King 1997). For example, public health researchers have long considered data aggregation problems a serious impediment to their research (Greenland 2004; Koopman 1977; Rose 1992; Schwartz and Carpenter 1999), and have dubbed the resulting inferential error "Type III

statistical error" (Schwartz and Carpenter 1999; but see Crawford et al. 1998; Leventhal and Huynh 1996; Marascuilo and Levin 1970). These problems are insidious because one actually finds a correct answer, but it is not for the question of interest (Schwartz and Carpenter 1999). Furthermore, these problems could bear substantial associated costs (Shrader-Frechette and McCoy 1992). For the gopher tortoise/URTD interaction, they could prevent increased understanding of the transmission of URTD. Additional studies employing the same design could not be employed as replicates to strengthen the answer to the question of interest, for example (see Johnson 2002; Palmer 2000; Underwood 1999). Worse, these problems could be detrimental to the well-being of the Gopher Tortoise. For example, one might infer from the very different conclusions of the two studies that no general relationship between risk of death from URTD and body size exists, when, in fact, URTD may selectively target relatively small adults. The ultimate result of this false inference could be failure to prevent the deaths of some of the most demographically valuable individuals. Data aggregation problems such as the one illustrated here probably are more common in ecological research than often recognized, but they may become more noticeable as ecological studies increasingly focus on the management of relatively small numbers of individuals in disturbed and fragmented landscapes.

Acknowledgments.—Gordon Fox, Gary Huxel, Henry Mushinsky, Robin Moore, and Sharon Schwartz provided comments on several versions of the paper. Sharon Schwartz also generously provided several important insights into the problem addressed here, from an epidemiologist's perspective. The research was conducted under FFWCC permit WX05107 and USF IACUC permit 1616.

Since the nineteenth century, melanism has attracted the attention of evolutionary biologists, who have focused their research on its evolutionary significance (Cook et al. 2005). Recent studies on mammals and birds corroborate the hypothesis that melanism has a genetic basis and that it is a powerful driver of species evolution (Eizirik et al. 2003; Mundy 2005). Nachman et al. (2003) provided a good example of the adaptive importance of melanism in Rock Pocket Mice, *Chaetodipus intermedius*, which, depending on the background, exhibits different colorations. In order to improve crypsis, light-colored mice live on light-colored rocks while melanistic mice live on dark lava rocks. Nachman et al. (2003) also demonstrated that melanism evolved independently in several mice populations and they found that different mutations located on different genes were responsible for melanism.

As in mammals and birds, melanism is quite common in reptiles (Jandzik 2004; Korsos and Nagy 2006; Mateo and López-Jurado 1994; Pérez-Mellado 1984; Trocsanyi and Korsos 2004; Zuffi 1986). Partial melanism is frequent and partially melanistic individuals typically have ventral scales, which are not completely black coloured (Trocsanyi and Korsos 2004). In some cases the populations of certain lizards and snakes are formed by a mixture of melanistic and normally coloured animals (Bittner and King 2003), while in other cases entire populations consist only of melanistic or only of normally colored animals (Daniels et al. 2004; Pearse and Pogson 2000). Melanism in *Lacerta* (*Zootoca*) *vivipara* has been described in central and northern Europe, but not in the Pyrenees nor in Spain (Cavin 1993; Kuranova 1989; Malkmus 1976; Petzold 1978; Westrin 1985, 1986). In comparison to other species (Thiesmeier 2002), melanistic Common Lizards occur at very low frequencies, indicating that melanism in the Common Lizard might be a rare rather than a well-established polymorphism. An explanation for its rarity might be high selective pressures acting against melanistic individuals (Andrén and Nilson 1981; Husak et al. 2006). Contrary to the rock pocket mice, melanistic and normally colored Common Lizards are usually observed in the same habitat and on the same background (Gvozdik 1999). Given that melanistic individuals lose the cryptic dorsal patterns, their dorsal coloration contrasts more with the background (Forsman 1995), making them more visible for predators (Husak et al. 2006). This suggests that melanistic individuals may suffer from increased predation risk (Andrén and Nilson 1981), potentially explaining their low frequency. Additionally, high predation risk may also result in decreased foraging efficiency and in increased physiological stress both negatively affecting body condition (Pérez-Tris et al. 2004; Rands and Cuthill 2001).

On the other hand, it is suggested that the potentially negative effects of melanism on viability and reproduction may be compensated, for example, through increased thermoregulatory capabilities (Gibson and Falls 1979; Rosenblum et al. 2004). This hypothesis is known as the "thermal melanism hypothesis" (Ellers and Boggs 2002; Parkash and Munjal 1999; Vences 2002). It has been shown to play an important role in many species, including eight lizard species (Daniels et al. 2004). The thermal melanism hypothesis predicts that melanistic individuals should have an advantage under conditions of low temperature since they heat up faster than light-coloured individuals (Clusella Trullas et al. 2007). This indicates that the advantage of melanism should increase with decreasing temperature and thus, that the frequency of melanism should increase with altitude (Clusella Trullas et al. 2007).

To test these hypotheses we used data from several Common

FIG. 1. Photograph of the melanistic *Lacerta vivipara* found in the Southern Pyrenees, Spain.

Lizard populations to estimate the frequency of melanistic lizards and we compared body condition and several morphological traits between melanistic and typically colored adult male Common Lizards of the same population.

On 19 April 2007, we found a completely melanistic male Common Lizard, *Lacerta (Zootoca) vivipara*, at the Puerto de Ibañeta, Navarra (Southern Pyrenees, Spain, 43.02158889ºN, 1.320416667ºW, elev. 1062 m). Although melanism has already been described in Europe for *L. vivipara*, this is the first time a melanistic individual has been described in the Pyrenees and also the first record for Spain. Thus it is the first record of a melanistic Common Lizard belonging to the oviparous clade, which mainly inhabits the Pyrenees and the Cantabrian mountains (Surget-Groba et al. 2001) and which may belong to a new species that hardly interbreeds with the Common Lizard (Heulin et al. 1989; Heulin et al. 1999). The melanistic adult male showed a uniformly black coloration (dorsally and ventrally), with a slightly blacker vertebral line (Fig. 1). The melanistic male was captured in a pre-alpine meadow whose predominant vegetation consists of *Ulex gallii* and *Erica vagans*. We discovered him in a small bush (*U. gallii*), in which we saw and captured several other conspecific lizards. To compare the melanistic individual with typically colored individuals of the same population, we captured an additional 54 adult males. Subsequent to the capture, all lizards were measured following Pérez-Mellado and Gosá (1988). For the analyses of body condition we used the residuals of the regression with SVL as the independent variable and body mass as the dependent variable (Wilson 1991). In order to compare the measurements of the melanistic individual with the other males of the same population, we applied Wilcoxon signed-ranks tests.

To estimate the frequency of melanistic individuals we analyzed data from the population where the melanistic lizard was captured and from six other populations from the Spanish Pyrenees (Provincia de Aragón) that we sampled during spring and summer 2007. The six populations were located at an average elevation of 1453 ± 94 m (range: 1140–1700 m). We captured a total of 515 *L. vivipara* and only one of these individuals was melanistic. Taking into account that not all observed lizards could be captured (captured to not-captured ratio is at most 1:3), we estimate that the frequency of melanistic individuals is maximally 1 per 2000 individuals. This estimate corresponds to a very conservative measurement because melanistic individuals are easier to detect, given that they stand out more against the surrounding vegetation (Andrén and Nilson 1981), and because in population censuses conducted in 2005 and 2006 (ranging from Vielha, Llerida, to Guipuzcoa) no melanistic lizards were observed.

The melanistic male did not significantly differ from the other males in body size, tail length, body condition, or in the number of scales (Table 1). Only the number of infralabial and collar scales was in the lowest percentile (0–10% percentile). Our results on body weight and snout–vent length agree with those obtained by Gvozdik (1999), who did not find differences between melanistic and typically colored common lizards.

The frequency estimation clearly shows that melanistic *L. vivipara* are rare in the Spanish Pyrenees. A potential explanation for the rarity might be provided by the thermal melanism hypothesis (Ellers and Boggs 2002; Parkash and Munjal 1999; Vences 2002). This hypothesis predicts that melanism should provide an advantage in cold climates. For example, in the Western Cape (South Africa) melanistic populations of cordylid lizards are associated with zones of upwelling cold water in the coast, or with mountainous zones with high incidence of fog and cloud cover (Mouton and Oelofsen 1988; Mouton et al. 2002). This hypothesis would also predict that melanism should be more frequent in mountainous habitats. However, our observations do not support this given that the observed melanistic individual was found in the Puerto de

Ibañeta population, which is located at the lowest elevation (1062 m), and no melanistic lizards were found in populations located at higher altitudes and thus in colder habitats. Further, capture effort was higher in the six other populations, which indicates that the frequency of melanistic individuals is likely much lower than in the Puerto de Ibañeta population. Consequently, it is unlikely that thermal advantages explain the observed frequencies. Furthermore, heating rates did not differ between melanistic and normally colored *L. vivipara* (Gvozdik 1999). It is also unlikely that melanism may have other advantages in the oviparous clade of the *L. vivipara*: i) melanism was rare; ii) melanism is genetically determined (King 2003; Majerus and Mundy 2003; Mundy 2007; Rosenblum et al. 2004); iii) slight selective advantages should rapidly translate into increased frequencies (Falconer 1960), in short-lived species such as *L. vivipara*. Alternately, the low frequency might be the result of strong selective pressures against melanistic individuals (Andrén and Nilson 1981). Given that the melanistic male was observed in the same habitat and on the same background as typically colored individuals, he should also be more conspicuous than normally colored individuals (Andrén and Nilson 1981; Forsman 1995). In comparison to typically colored individuals, detection of the melanistic male was markedly easier. However, we could not find evidence that higher conspicuousness might have resulted in decreased body condition (Forsman 1995; Perez-Tris et al. 2004). Further, most of the measured traits were in the 10–90% percentile and only two of fourteen morphological measurements were in the 0–10% percentile. This suggests that the observed melanistic male did not differ from typically colored males in traits other than coloration. Melanism usually results from mutations (Majerus and Mundy 2003; Mundy 2007; Rosenblum et al. 2004) and it has been suggested that in some species melanism is controlled by neutral alleles (Nahrung and Allen 2005), which are maintained at a constant low level. Given that we found no evidence for positive or negative selection, our results are in line with the neutral allele hypothesis, which states that black alleles are not eliminated by natural or sexual selection because black alleles are neither favorable nor unfavorable to survival or reproduction (Nahrung and Allen 2005). This hypothesis might also explain why the frequency of melanistic animals is very low in the Spanish Pyrenees. However, to understand the reasons why melanistic Common Lizards might be very rare, further sampling needs to be carried out to increase the sample size and thus the analytical power.

Acknowledgments.—We thank Borja Milá for proofreading. The capture and handling of the lizards was conducted under license provided by the Dpto. Medio Ambiente, Ordenación del Territorio y Vivienda of the Government of Navarra and the Departamento de Medio Ambiente of the Goverment of Aragón. L.M. Large size, generalist eating habits, and high reproductive capacity have made the Bullfrog (*Rana catesbeiana*) an extremely successful invader and important competitor with native species of amphibians (Hecnar and M'Closkey 1997). Increased specialization, competitive inferiority, and predation by Bullfrogs make native species susceptible to declines (Mayuri et al. 2004). Introduction of Bullfrogs has contributed to the decline of native species of *Rana* in western North America (Bury and Luckenbach 1976; Clarkson and DeVos 1986; Hammerson 1982; Moyle 1973). *Rana catesbeiana* is a recently introduced species to the Andean region of Mérida, Venezuela (Barrio 2001) although anecdotal evidence suggests this species has has been present since the mid-1980s. Further, in this introduced population, the pathogen *Batrachochytrium dendrobatidis*, the agent for chytridomycosis, has been identified in 96% of healthy individuals (Hanselman et al. 2004). This infectious fungal disease is responsible for mass mortality in amphibian species worldwide (Ron and Merino 2000).

Because introduced Bullfrogs have proven to negatively impact native frog populations in other regions, the discovery of Bullfrogs in the Andes of Venezuela prompted us to undertake a variety of studies on their ecology to determine the extent of their impacts on native frog populations. Here, we report the diet of Bullfrogs from a recently established population.

This study was conducted at a 1 km^2 pond in a location known as "La Carbonera" (8.6148333°N, 71.3630556°W, 2360 m elev.), 30 km NW of Mérida city, located in the "Cordillera de Mérida" in the Andes of Venezuela. The surrounding habitat consists mostly of secondary forest (Díaz de Pascual and Chacón-Ortíz 2001).

The Bullfrog was the most common frog in the pond, and was found extensively throughout and around the pond. Fieldwork was conducted monthly from March to November 2002. Large Bullfrogs were captured by air-rifle and small ones by hand and net. Immediately after capture, we measured snout–vent length (SVL; to the nearest 0.1 mm) and mass (to the nearest 0.1 g). Frogs were dissected, the stomachs were removed and the contents placed in 10% formalin for later analysis. Bullfrogs that contained at least one prey item in their stomachs (N = 338) were divided into four categories based on size and morphological characters: 1) Recently-metamorphosed: legs fully developed and tail partially absorbed; 2) Juveniles: tail completely absorbed, 51–69 mm SVL; 3) Sub-adults: 70–103 mm SVL; and 4) Adults: 104–180

mm. In the sample of 338 individuals, we had 90 recently metamorphosed, 92 juveniles, 77 sub-adults, and 79 adults.

Organisms in the stomach analysis were classified as adults or immature stages to the family level according to Smith and Silva (1983). Diet was quantified as the number and volume of prey individuals and then was scored to order level. Prey length was also measured with a dial caliper to the nearest 0.01 mm. Prey volume was determined by use of the water displacement method (precision of 0.1 cc). We determined volumetric and numeric percentages of each prey per frog size category as follows: % volume = (Total volume of diet item) × 100 ÷ (Total volume of all items). % N = (Number of samples containing diet item) × 100 ÷ (Total number of all items). These two measurements provide different insights into the feeding habits. To integrate them we calculated an index of relative importance of each prey as the average of numeric and volumetric percentages of prey items per each frog size-category.

Food niche width, which characterizes the food resource spectrum used by Bullfrogs in each size category, was calculated based on the index of relative importance described above. Niche overlap among frog size categories was calculated using the program "Niche Measures" (Krebs 2002). A one-way ANOVA and a post-hoc Bonferroni test were performed to examine differences among frog size categories and prey size. Pearson correlation analysis was used to examine the relationship between frog size (SVL) and prey size. Statistical analyses were performed using SPSS statistical package ver. 10 for Windows (User's Guide, Cary, SPSS Inc., NC, 1999).

We identified 474 prey items from stomach contents. Means and standard deviation of all measurements obtained from all frogs in each size category are given in Table 1. Terrestrial prey constituted a greater proportion of the diet for recently metamorphosed individuals and juveniles, compared to sub-adults and adults (Table 2). This may be a result of differential habitat use among the age classes as adults are known to use more aquatic habitats than juveniles (Werner et al. 1995). Vertebrates found in the stomach contents were mainly *Poecilia reticulata*, *Rana catesbeiana*, *Leptodactylus meridensis*, and *Hyla meridensis*. Juvenile Bullfrogs were the largest diet item and were common in adults and sub-adults. The frequencies of occurrence of conspecifics in the stomach contents were less in sub-adults (5%) and higher in adults (32%). Most conspecifics were smaller individuals (SVL < 50 mm).

Niche breath decreased from 0.93 for recently metamorphosed to 0.77 for adults (Table 2), indicating a tendency for less generalized feeding as bullfrogs grow. Juveniles had a higher diet overlap with recently metamorphosed and sub-adults 64% and 60%, respectively. Lower overlap of 54% was obtained between sub-adults and adults (Table 3).

Following log-transformations, variable variances among groups were not homogeneous (Levene statistic = 12.38, p = 0.000). However, we chose to use parametric statistical methods because of large sample sizes (Zar 1999). ANOVA detected significant differences among prey size and frog size category ($F_{3, 334}$ = 45.02,

TABLE 1. Snout–vent length (SVL) and mass of 338 *Rana catesbeiana* from the Andes of Venezuela and the corresponding morphological variables of the prey items.

Class Size	SVL (mm) Mean ± SD	Mass (g) Mean ± SD	Prey Number Mean ± SD	Prey length (mm) Mean ± SD	Prey volume (mm^3) Mean ± SD
Rec. Met.	56.54 ± 4.54	28.20 ± 2.97	1.74 ± 1.49	10.61 ± 2.79	0.14 ± 0.06
Juveniles	60.62 ± 7.24	30.67 ± 8.60	1.85 ± 1.71	11.10 ± 5.26	0.34 ± 0.32
Sub-adults	85.26 ± 10.58	74.47 ± 26.41	2.59 ± 1.86	15.48 ± 8.51	1.95 ± 6.44
Adults	142.65 ± 15.08	415.39 ± 117	1.39 ± 0.85	34.21 ± 22.09	13.94 ± 15.59

Sample size	90	92	77	79

TABLE 3. Diet overlap index among *Rana catesbeiana* size class groups and overlap percentages (in parentheses). Rec-met. = recently metamorphosed.

Size Class	Rec-met.	Juveniles	Sub-adults	Adults
Rec-met.	-	0.79 (64%)	0.54(39%)	0.18 (27%)
Juveniles		-	0.76 (60%)	0.20 (36%)
Sub-adults			-	0.64 (54%)

P = 0.000) and pos-hoc Bonferroni test found significant mean differences between adults and all other categories ($\alpha = 0.05$). There was significant and positive relationship between Bullfrog length (SVL) and prey length (r = 0.578, N = 338, P = 0.01). Bullfrog size explained only 33% of the prey size variability. The remainder of the variation is probably due to other factors including behaviour, physiological needs, prey availability and habitat use.

Rana catesbeiana has a generalist diet, but probably has a preference for some prey items such as Odonata, Coleoptera, Hymenoptera, and vertebrates (fish and frogs). There was a tendency to increase vertebrate consumption as bullfrog size increased. It was observed mainly in large frogs (sub-adults and adults). Cannibalism can have strong effects on reducing population size and community structure (Fox 1975).

The diet of Bullfrogs introduced into Colombia mostly consisted of insects (56%), with vertebrates constituting only 2% of the diet (Daza and Castro 1999). However, in Japan it was found that adults fed mainly on crayfish (49.6%) with vertebrates not represented in the diet (Hirai 2004).

Our results confirmed that *R. catesbeiana* is an opportunistic species, with both invertebrates and vertebrates comprising the diet. Differences in diet are related to differences in body size and microhabitat selection (Wu 2005). This invasive species may affect native amphibians as predators, competitors, agents of habitat change, and disease reservoirs. Therefore, management and control should be attempted.

Salmonella is a zoonotic bacterium that causes gastrointestinal disease in humans and can be carried asymptomatically by animals (Chiodini and Sundberg 1981). While most human infections are caused by the consumption of contaminated food (Tauxe 1991), reptiles are also a source of infection and may cause as many as 70,000 human cases annually in the United States (Mermin et al. 2004). Public health concerns have led to studies to identify the rate of *Salmonella* shedding in captive turtles from zoos (Otis and Behler 1973), commercial turtle farms (Siebeling et al. 1984), and private collections (Abalem de Sá and Solari

2001). Comparatively little is known, however, about *Salmonella* infections in wild, free-ranging turtles. Generally, wild turtles are believed to shed *Salmonella* at lower rates than captive turtles because they either lack exposure to stressors that increase shedding rates or because they are not natural carriers of the bacterium (Du Ponte et al. 1978; Richards et al. 2004; Saelinger et al. 2006). A few recent studies on wild chelonians have, however, reported a high prevalence of *Salmonella* in turtles (Chambers and Hulse 2006; Gaertner et al. 2008), with wild turtles having similar prevalence of *Salmonella* infection to captive turtles (Gaertner et al. 2008).

We examined the prevalence of *Salmonella* in wild Red-eared Sliders (*Trachemys scripta elegans*). Red-eared Sliders are common in the pet trade, and numerous studies have quantified *Salmonella* shedding rates in this species in captivity (Abalem de Sá and Solari 2001; Chassis et al. 1986; McCoy and Seidler 1973; Otis and Behler 1973; Pasmans et al. 2002a). They are also notorious as a globally invasive species, and they inhabit a variety of aquatic habitats. Our goal was to estimate the prevalence of *Salmonella* in wild Red-eared Sliders in Illinois where they inhabit a variety of natural water bodies and man-made agricultural ponds. We hypothesized that the prevalence of *Salmonella* in turtles would differ among habitat types because turtles might have experienced persistent stressors in man-made habitats, which might have increased shedding rates, or because man-made habitats might have increased infection risk directly. Such a result would have public health implications, and might help to explain variation in shedding rates observed among previous studies of wild turtles.

Turtles were sampled from water bodies in southern Illinois, a region characterized primarily by a mosaic landscape of forest, grassland, and intensive row crop agriculture. Five natural ponds (37.0688°N–37.1080°N, 88.5934°W–88.4677°W; NAD83) and five artificial ponds were sampled (37.4622°N–37.4089°N, 88.6900°W–88.6508°W; NAD83). Natural ponds, oxbow lakes along the Ohio River floodplain, were large (mean ± S.E.: 28.4 ± 11.5 ha), and supported a high diversity of fishes (Readel, unpubl. data) as well as diverse turtle assemblages (Dreslik et al. 2005). Artificial ponds, built in the 1970s as agricultural retention ponds, were small (1.1 ± 0.3 ha), contained only common lentic turtle species, and have been stocked with game fish (Readel, unpubl. data). Both habitat types were used as public or semi-public fishing grounds, and Red-eared Slider turtle abundance (trap-hours required to capture one turtle) was similar between sites (natural: 33.8 ± 9.5; manmade: 41.5 ± 13.7; Readel, unpubl. data).

Turtles were captured using baited hoop traps and were held in individual bleach-decontaminated tubs up to 4 h until sampling. Cloacal swabs were collected from turtles by rubbing a sterile polyester swab against the inner cloacal lining to obtain fecal material. Each swab was then agitated into 10 mL of selenite cystine broth (Edge Biologicals, Memphis, Tennessee, USA) that was incubated for 18 h at 37°C and then plated on xylose lysine desoxycholate (XLD) agar (Edge Biologicals, Memphis, Tennessee, USA) to isolate individual bacterial colonies. Plates were incubated at 37°C for 24 h and suspect colonies (colonies morphologically consistent with *Salmonella*) were inoculated into 0.2 ml tubes containing tryptic soy agar (Becton, Dickinson and Company, Sparks, Maryland, USA) for transport to the laboratory. If suspect colonies were not present after 24 h, plates were incubated at room temperature for an additional 24 h. Colonies were re-streaked on XLD agar and re-isolated in the laboratory.

All suspect colonies were subjected to a diagnostic PCR for *Salmonella*. Isolated colonies were inoculated into 0.5 ml of Luria-Bertani broth (Becton, Dickinson and Company, Sparks, Maryland, USA), which was incubated for 18 h at 37°C. Bacterial cells were then pelleted by centrifugation, and DNA was extracted using the DNeasy Mini Kit (Qiagen, Valencia, California, USA) eluted in a 100 μl volume, according to the manufacturer's protocol. The *Salmonella* specific primer pair invA-1 (5'- ACAGTGCTCGTTTACGACCTGAAT) and invA-2 (5'- AGACGACTGGTACTGATCGATAAT) was used to amplify a 243-bp segment of the *Salmonella* invA gene, which has been shown to be both sensitive and specific for this bacterial genus (Chiu and Ou 1996). As an internal control for DNA extraction and amplification, another published PCR primer pair of 16S-F (5'- AGACTGCTACGGGAGGCAGCAGT) and 16S-R (5'- GTTGCGCTCGTTGCGGGACTTAA) was used to amplify a 755-bp fragment of the 16S ribosomal RNA subunit gene, which is present in all bacteria (Villalobo and Torres 1998). PCRs were conducted in 12.5 μl volumes containing 1X DyNAzyme EXT buffer (Finnzymes OY, Finland), 3.5 mM MgCl2, 200 μM dNTPs, 0.3 μM each of primers 16S-F and 16S-R, 0.06 μM each of primers invA-1 and invA-2, and 0.125 units of DyNAzyme EXT DNA polymerase (Finnzymes OY, Finland). Reactions were cycled in an i-Cycler thermocycler (BioRad Inc, Hercules, California, USA) at 94°C for 2 minutes, then for 30 cycles at 94° C for 30 seconds, 57°C for 30 seconds, and 72°C for 45 seconds, followed by a final 72°C 4-minute extension step and an indefinite 4°C soak. A sample of wild-type *Salmonella typhimurium* DNA from the University of Illinois Veterinary Diagnostic Laboratory was used as a positive control, and sterile, distilled water was used as a negative control. Amplicons were visualized by electrophoresis in 1.5% agarose /TAE buffer followed by ethidium bromide staining and digital imaging under ultraviolet light. Samples were considered positive only if PCR produced both the 243-bp invA band and the 755-bp internal control 16S rRNA band. To confirm amplification of the correct gene, one invA PCR product from the positive control isolate was purified using the Zymoclean Gel DNA Recovery Kit (Zymo Research, Orange, California, USA) and submitted to the University of Illinois, Biotechnology Center for sequencing. The resulting sequence was compared to published sequence data (BLAST tool from the National Center for Biotechnology Information).

One hundred wild Red-eared Sliders were captured between June 18–29, 2006. Fifty turtles were captured from natural ponds and an equal number were captured from artificial ponds. Suspect colonies (colonies that were morphological consistent with *Salmonella* on XLD agar) were recovered from nine of 50 turtles in natural ponds and 12 of 50 turtles in artificial ponds.

PCR testing of suspect colonies failed to yield amplicons of the invA gene in any suspect colony, although amplifications of the internal control 16S rRNA fragment yielded positive results in all cases. Our *Salmonella* positive control yielded amplicons of both invA and 16S, and DNA sequencing confirmed that we had indeed amplified invA. These results demonstrated that DNA extraction and PCR were universally successful. The prevalence of

Salmonella spp. in the turtles sampled was therefore 0%, with an upper 95% confidence limit of 4.4% for the entire population of 100 turtles (calculated using the modified Wald method; Agresti and Coull 1998). All suspect colonies were, therefore, likely to be normal enteric organisms that produce hydrogen sulfide.

The absence of *Salmonella* in wild turtles in our study was consistent with findings of other studies on wild turtles in the United States that have reported a prevalence of 0–8% (Brenner et al. 2002; Harwood et al. 1999; Jackson et al. 1969; Richards et al. 2004; Saelinger et al. 2006), but was lower than those reported from Spain (12–15%; Hidalgo-Vila et al. 2006), Pennsylvania (100%; Chambers and Hulse 2006), and Texas (51%; Gaertner et al. 2008). Studies on captive turtles have reported *Salmonella* in 12–41% of *T. scripta* (Abalem de Sá and Solari 2001; Chassis et al. 1986; McCoy and Seidler 1973; Otis and Behler 1973; Pasmans et al. 2002a), and in 3–72% of all turtle species (Abalem de Sá and Solar 2001; Cambre et al. 1980; Corrente et al. 2004; Geue and Löschner 2002; Jackson and Jackson 1971; Nakadai et al. 2005; Onderka and Finlayson 1985; Otis and Behler 1973; Pasmans et al. 2002a). Our results supported the conclusion that the prevalence of *Salmonella* is low in wild compared to captive turtles.

Turtles might be natural carriers of *Salmonella*, but rarely shed the bacterium unless physiologically stressed (Du Ponte et al. 1978; Richards et al. 2004; Saelinger et al. 2006). In this study, artificial habitats were not associated with increased shedding in wild Red-eared Slider turtles. The habitats in which our turtles resided might not have experienced stress levels high enough to activate shedding. Alternatively, wild turtles may not be natural carriers of *Salmonella*, but rather only become infected through their environment (Richards et al. 2004; Saelinger et al. 2006). For instance, wild turtles admitted to a veterinary hospital were not shedding *Salmonella* upon entrance or after three weeks in captivity, and gastrointestinal mucosal samples from dead or euthanized wild turtles were also negative (Saelinger et al. 2006), suggesting that these turtles were not carriers of *Salmonella* before capture (Saelinger et al. 2006). Our results were consistent with another study that found no effect of habitat on the prevalence of *Salmonella* in aquatic turtles (Gaertner et al. 2008).

Our methods might have limited our ability to detect turtles with occult *Salmonella* infection, because we did not sacrifice turtles and sample regions of their gastrointestinal tracts where *Salmonella* can reside (Pasmans et al. 2002b). However, we used methods that were similar to previous studies (Corrente et al. 2004; Saelinger et al. 2006). Corrente et al. (2004), for example, showed that the quantity of feces on swabs was not correlated with a greater recovery rate, because of the efficiency of the enrichment step. Repeated culture with several media over time may have increased our chance of detecting intermittently shed organisms like *Salmonella* (Smith et al. 2002). Nevertheless, our failure to detect *Salmonella* in any of the 100 turtles indicated that, if the bacterium existed in this population, its point prevalence was below 4.4%.

Overall, our results were consistent with previous observations that wild turtles have low prevalence or shedding rates of *Salmonella*, and that these rates are lower than in captive turtles. To the extent that our results can be generalized, the public health problem of zoonotic salmonellosis of turtle origin may be largely characteristic of farmed and otherwise captive turtle populations; wild turtles may not represent an important source of the bacterium, even in habitats that are artificial and/or impacted by human activity. Red-eared Sliders, a notoriously ecologically plastic (and globally invasive) species, may be able to adapt to areas of high human impact without serious health-related consequences. It remains to be seen whether other, less adaptable turtle species show similar patterns.

Acknowledgments.—This research was supported by the Illinois Department of Natural Resources Wildlife Preservation Fund, Sigma Xi, the Chicago Herpetological Society, the Illinois State Academy of Sciences, the R. Weldon Larimore/Jordan Creek Endowment Fund, and the University of Illinois Program in Ecology and Evolutionary Biology. The authors thank F. Estus for logistic assistance with field work, and E. Estoff for assistance in the laboratory. All research was conducted in accordance with University of Illinois, Urbana-Champaign IACUC protocol # 06171.

Lizards of the genus *Tropidurus* occur throughout South America, mainly in open habitats such as Caatinga and Cerrado, occupying a wide variety of microhabitats (Rodrigues 1987). Many *Tropidurus* species (e.g., *T. oreadicus*, *T. hispidus*, *T. torquatus*, and *T. etheridgei*) are abundant, widespread, and ecologically diverse (Rodrigues 1987). *Tropidurus* are diurnal, heliophilous, sit and wait predators, consuming a wide variety of arthropods and occasionally vertebrates (Bergallo and Rocha 1993; Colli et al. 1992; Rocha and Siqueira 2008). With few exceptions, reproduction of *Tropidurus* species is non-continuous, occurring during the dry-wet season (Van Sluys et al. 2002) and involves a sexual dimorphism, both in color and size (Wiederhecker et al. 2002).

Although several aspects of life history of some *Tropidurus* species have been studied (e.g., Bergallo and Rocha 1994; Carpenter 1977), little is known about geographic variation in ecological attributes of the widely distributed species *T. etheridgei*.

Wide-ranging lizards often exhibit geographic variation in life-history and ecological traits (Qualls and Shine 1997). Understanding sources of this variation is essential for understanding the success and evolution of lizard species (e.g., Vitt and Colli 1994). Moreover, modification or the maintenance of ecological attributes between different populations of the same species may indicate the influence of historical or ecological factors on the structure of lizard communities (Vitt et al. 1998).

Tropidurus etheridgei is a medium-sized lizard distributed in the dry habitats of the Chaco, the Cerrado and the Pantanal regions, in Brazil, Paraguay, Bolivia and Argentina (Cei 1993; Rodrigues 1987). In spite of following the same patterns of other *Tropidurus* with a seasonal reproductive cycle, sexual dimorphism in color and shape and a generalized diet, there are some differences in the biology of *T. etheridgei* between the Chaco (Cruz 1997; Cruz et al. 1998) and the Cerrado (Vitt 1991) populations, mainly with respect to diet, reproduction and habitat use. However, information about populations in these two regions is limited. Herein, we describe the reproduction and diet of *T. etheridgei* in rocky areas of the Pantanal, Western Brazil. In addition, we compare reproductive and feeding data to those reported for *T. etheridgei* in the Chaco and the Cerrado regions.

Materials and Methods.—The study was conducted in three rocky areas (19.1802778°S, 57.5381111°W; 19.1672222°S,

57.5573056°W; 19.0709167°S, 57.4858889°W) in the municipality of Ladário, Mato Grosso do Sul state, Brazil. The area is characterized by rock substrate covered mainly by bromeliads (*Deuterochomia* sp. and *Bromelia balansae*) and patches of dry forest. The climate is characterized by an Aw type of Köppen classification, with mean precipitation of 1120 mm, concentrated in October–March (Soriano 1997).

Lizards were captured from July 1997 to June 1998 by noose or hand, with a sampling effort of 36 h/month. The following variables were measured for each lizard: snout–vent length (SVL), head length (HL), head width (HW), head height (HH), body width (BW), body height (BH), tail length (TL), foreleg length (FL) and hind leg length (LL) using an electronic caliper (Mitutoyo®; ± 0.1 mm). Lizard body mass was measured with Pesola® spring scales (± 0.2 g).

To examine morphological variation due to sex, we log-transformed all morphometric variables of adult individuals and made separate regressions of all variables with log10 SVL. We then used a multivariate analysis of variance (MANOVA) on the residuals of the regressions, with the sex as factor. The differences in SVL of males and females were tested by a Mann-Whitney Z test.

For diet analysis, the lizards were with an injection of Thiopental® dissected, stomachs removed, and prey items identified to the lowest taxonomic level possible. The length (l) and width (w) of intact prey were recorded with electronic calipers and prey volume (V) was estimated as an ellipsoid:

$$V = \frac{4}{3\pi\left(\frac{1}{2L}\right)\left(\frac{1}{2W}\right)^2}$$

where L is the prey length and W is the prey width.

Numeric and volumetric percentages of each prey categories were calculated for allow comparisons with other studies and for calculations of niche breadths, which were computed using the inverse of Simpson's diversity index (Simpson 1949):

$$\beta = \frac{1}{\sum_{n=1} pi^2}$$

where *p* is the numeric or volumetric proportion of prey category *I*, and *n* is the number of categories. In addition, a standardized niche breadth (niche breadth divided by number of prey categories) was calculated for comparisons between the populations of *T. etheridgei* from Chaco (Cruz et al. 1998) and Cerrado (Vitt 1991). To investigate the relationship between lizard SVL and mean prey length we performed a Pearson correlation.

Lizards were sexed by dissection and gonads were examined. Males (N = 8) were considered reproductive if they contained convoluted epididymides. Females (N = 17) with vitellogenic follicles (N = 14) or oviductal eggs (N = 3) were considered reproductively active. Simultaneous presence of vitellogenic follicles and eggs was considered as an indication of production of more than one clutch per reproductive season.

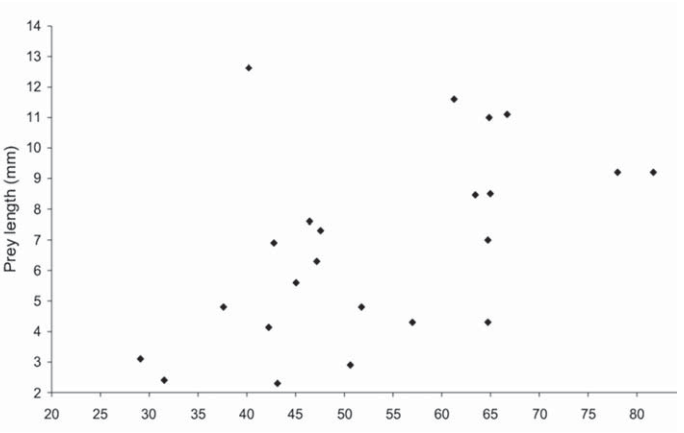

FIG. 1. Relationship between mean prey length and snout–vent length (SVL) of the lizard *Tropidurus etheridgei* in rocky areas of central Brazil.

Size at sexual maturity was estimated as the smallest female containing vitellogenic follicles and the smallest male with convoluted epididymides. Length and width of testes and follicles and/or eggs were recorded with a digital caliper and volume was estimated using the ellipsoid formula described above.

Results.—Reproduction and diet of *T. etheridgei* are based on 31 individuals: 8 adult males, 17 adult females and 6 juveniles. No sexual dimorphism in SVL for 8 adult males (54.70 ± 12.86 mm) and 17 adult females was detected (54.29 ± 13.95 mm) (Mann-Whitney U test = 62, P = 0.75). Likewise, no sexual dimorphism for body shape between the sexes was verified (Wilks $\lambda = 0.50$; $F_{8,16} = 1.99$; P = 0.11; N = 25), although some variables, such as tail length were different (Table 1). The smallest mature male was 47.6 mm in SVL and the smallest mature female was 42.8 mm. Mean clutch size based on three females was 4.33 ± 2.08, and mean egg volume was 186.02 ± 108.21 mm^3 (N = 13 eggs). None of these females contained evidence of production of more than one clutch. Females with oviductal eggs (N = 3) were captured from October–December and skin in the gular region was dark, in contrast to the grayish gular region of non-gravid females from January–September.

Of the 31 stomachs of *T. etheridgei* dissected, 25.8% (8) were empty. We identified 17 prey types (N = 779 items) that were

TABLE 1. Summary of descriptive statistics (range) of 17 adult female and 8 adult male *Tropidurus etheridgei* from rocky habitats of the Pantanal, Brazil. Means are ± 1 standard deviation.

Variables	Males	Females
SVL	54.70 ± 12.86 (47.57–81.57)	54.29 ± 13.95 (42.79–78.01)
Body width	13.52 ± 4.05 (10.44–19.66)	14.25 ± 4.3 (10.44–20.29)
Body height	8.13 ± 2.32 (7.65–12.57)	9.08 ± 3.62 (5.54–16.03)
Head width	15.86 ± 3.68 (9.96–18.22)	15.31 ± 3.27 (8.76–13.29)
Head length	11.04 ± 2.97 (13.91–23.48)	10.27 ± 2.27 (12.68–20.48)
Head height	7.92 ± 1.74 (6.76–11.18)	7.86 ± 2.20 (6.03–11.99)

TOTAL	779	100	5951.32	100
NICHE BREADTH		1.74		4.90

mainly insects (83.7% in volume), although arachnids comprised 13.65% of the total volume and spiders were the second most frequent prey type in number (5.13%). Ants were the most frequent in number (75.22%) and Orthoptera was greatest in volume (35.26%; Table 2).

Niche breadth of *T. etheridgei* was 1.74 in number and 4.90 in volume. Mean number of prey was 28 ± 22.53 (4–89), with a mean length of 3.39 ± 2.75 mm (N = 639), mean width of 1.14 ± 1 mm and a mean volume of 9.94 ± 42.27 mm^3. Mean prey length was significantly correlated with lizard SVL ($r = 0.29$, $P < 0.001$; Fig. 1).

Discussion.—Many aspects of the ecology of *T. etheridgei* in the Pantanal were similar to those of the Chaco and Cerrado populations (Table 3). However, some differences regarding reproduction were apparent. Clutch size of *T. etheridgei* from the Pantanal is smaller than that of lizards of the Chaco and the Cerrado regions. Furthermore, the Cerrado and Chaco populations produce multiple clutches (Cruz 1997; Vitt 1991). However, absence of multiple clutches and the low clutch sizes in the present study may be due to our sample size. Environmental factors, such as rainfall, strongly affect reproductive characteristics of lizard populations at the local level (Colli 1991; Van Sluys et al. 2002). Mesquita and Colli (2003) found that populations of *Cnemidophorus* in highly seasonal biomes (Cerrado and Amazonian Savannas) produce larger clutches and have a shorter reproductive season than in habitats with unpredictable climates (Caatinga). This may partially explain the cyclical reproductive season in the Pantanal (with a highly seasonal climate), but not clutch size. Clutch size is influenced by female body size and microhabitat preferences (Vitt 1981). Rocky habitats may also constrain the availability of prey, which ultimately can affect energy invested in reproduction (Vitt et al. 1996).

Dark gular patches in gravid females were reported for the second time for a *Tropidurus* species. These occur in *T. chromatops* (a species that resembles *T. etheridgei*) from Serrania de Huanchaca, Bolívia (Harvey and Gutberlet 1998). Dichromatism most likely provides signals in social interactions. The lack of sexual size dimorphism found here may result from our small sample size, since many larger males were observed in the field. Male *Tropidurus* generally have larger SVL than females (Vitt 1993; Vitt et al. 1996). This includes the Chaco populations, where males are considerable larger than females (Cruz 1997).

The diet of *T. etheridgei* in the Pantanal consisted almost exclusively of arthropods, with a high percentage of ants. However, lizards from the Chaco population (Cruz et al. 1998) also feed on vertebrates. Similarly to the Chaco lizards, we did not find flowers in the diet of *T. etheridgei*, in contrast to the diet of the Cerrado population where this was an important item, although we collected year-round (Vitt 1991). In spite of this, the diet is similar among populations, being ants, beetles and larvae the most important prey items. Differences in diet between populations may reflect geographic variation in prey availability, seasonality and dietary preferences (Mesquita and Colli 2003). Moreover, the diet of *T. etheridgei* follows the general pattern found in many species of *Tropidurus*, with a consumption of a great variety of prey, especially a lot of ants (Vitt et al. 1997). They also occasionally prey on vertebrates, including conspecifics (Kiefer and Sazima 2002). This can be confirmed by the high values of niche breadth found in many *Tropidurus* species, although in our study the niche breadth values, both numerically and volumetrically resembles the Chaco populations studied by Cruz et al. (1998).

With the exception of differences related to clutch size and few

TABLE 3. Ecological comparisons of *Tropidurus etheridgei* in three different biomes of South America: Chaco (Cruz 1997; Cruz et al. 1998; Fitzgerald et al. 1999), Cerrado (Vitt 1991), and Pantanal (this study). Sample sizes are in parentheses.

	CERRADO	PANTANAL	CHACO
Mean SVL (mm)	68.9 (71)	62.0 (31)	68.9 (150)
% volume of ants in diet	36.6	7.64	27.11
Mean prey length (mm)	4.7 (117)	3.39 (639)	9.14 (386)
Numeric niche breadth	0.21	0.10	0.16
Volumetric niche breadth	0.47	0.29	0.27
Mean clutch size	4.9 (45)	4.3 (3)	6.2 (15)
Multiple clutches	yes	no?	yes

prey types, the biology of *T. etheridgei* is similar in three different biomes of South America. However, further studies are necessary to identify the influences of historical and ecological factors in the differences.

Acknowledgments.—We thank Monique Van Sluys, Daniel O. Mesquita, Felix B. Cruz, Laurie J. Vitt and one anonymous reviewer for their comments on earlier drafts of this manuscript. We also thank Nicola Conran Zorzetto for help with the English version. This study was partially funded by PROPP/UFMS and CNPQ. We thank IBAMA for permission (proc. no. 2747/98 – 74 MS). RWA thanks CAPES for a grant.

Vertebrate gastrointestinal tracts (GITs) are complex ecosystems inhabited by hundreds of microbial species (Bäckhed et al. 2004; Lu and Walker 2001). Vertebrates have coevolved with commensal and mutualistic microbes and microbiota is now considered an essential component of mammalian physiology (Dethlefson et al. 2007).

Microbial cells living in and on the human body are estimated to outnumber human cells by a factor of ten (Turnbaugh et al. 2007). The use of molecular techniques to study the human microbiota is revolutionizing the study of human biology (Dethlefsen et al. 2007). Bacteria of the GIT have an important influence on nutritional, physiological, and immunological processes of their hosts and provide multiple benefits (Turnbaugh et al. 2006; Zoetendal et al. 2004). In humans, beneficial bacteria synthesize vitamins, break down indigestible substances, and provide protection from the colonization of pathogenic bacteria by competing for food and living space or by producing antimicrobial substances (Xu and Gordon 2003). Mutualistic and commensal bacteria play a key role in educating the immune system to provide tolerance and reduce allergic responses (Braun-Fährlander et al. 2002). The intestinal microbiota also has a profound affect on nutrient acquisition. Mouse GIT microbiota suppress gene expression of factors produced by the intestinal epithelium and promote absorption of monosaccharides resulting in increased fat storage (Bäckhed et al. 2004). Turnbaugh et al. (2007) recently wrote, "To understand the range of human genetic and physiological diversity, the microbiome and the factors that influence the distribution and evolution of the constituent microorganisms must be characterized." Surely the importance of microorganisms is not restricted to humans and an understanding of microbe host relationships in vertebrates is critical to understanding their biology and ecology.

Snakes, especially pitvipers, are useful organisms for studies of vertebrate energy budgets (Beaupre 1996, 2002). Microbiota of the GIT are likely to play an integral role in nutrient and energy acquisition in snakes, yet very little is known about the microbial communities of snake GITs and nothing is known about the function of microorganisms for nutrient acquisition in snakes. An understanding of the diversity and function of intestinal flora of snakes is likely to increase our knowledge of nutrient acquisition and energy budgets in these animals.

Gastrointestinal microbiota have been relatively well studied in humans (Hooper et al. 2001; Wang et al. 2003), lab mice (Bäckhed et al. 2004), and agriculturally important animals (Leser et al. 2002; Simpson et al. 2002). Less is known about the GIT microbiota of non-human and non-agricultural taxa and the implications of GIT microbiota for studies of ecophysiology have yet to be explored. Despite their importance to ecophysiological research, virtually nothing is known about the structure and function of microbial communities in reptile GITs. To date, only the microflora of the mouth, esophagus, and feces of snakes have been characterized using traditional microbiological (culturing) techniques (Graves et al. 1988; Grupka et al. 2006; Lutterschmidt et al. 2007). Because culture-based techniques fail to cultivate many microbial species (Raskin et al. 1997; Ricke and Pillai 1999), their use may drastically underestimate microbial diversity. Furthermore, to fully understand the structure and function of the microbial communities in reptilian guts, all organs of the digestive tract should be studied. From an energy acquisition standpoint the small intestine is especially important because nutrient absorption occurs there.

Molecular techniques for identifying complex microbial communities can alleviate problems associated with traditional culturing techniques because selective cultivation and isolation conditions are not needed. Denaturing gradient gel electrophoresis (DGGE) is a commonly used culture-independent technique for modeling complex microbial communities (Ercolini 2003). To determine bacterial species diversity of a sample using DGGE, DNA is extracted from the sample. The polymerase chain reaction (PCR) is then used to amplify the 16s rRNA gene, present in all bacteria, and produce products of the same size but with different sequences (Muyzer et al. 1993). The products are subsequently separated on a denaturing gel with an increasing gradient to produce a banding pattern unique to each bacterial community sampled. Individual bands obtained during electrophoresis may be excised and sequenced. Sequences

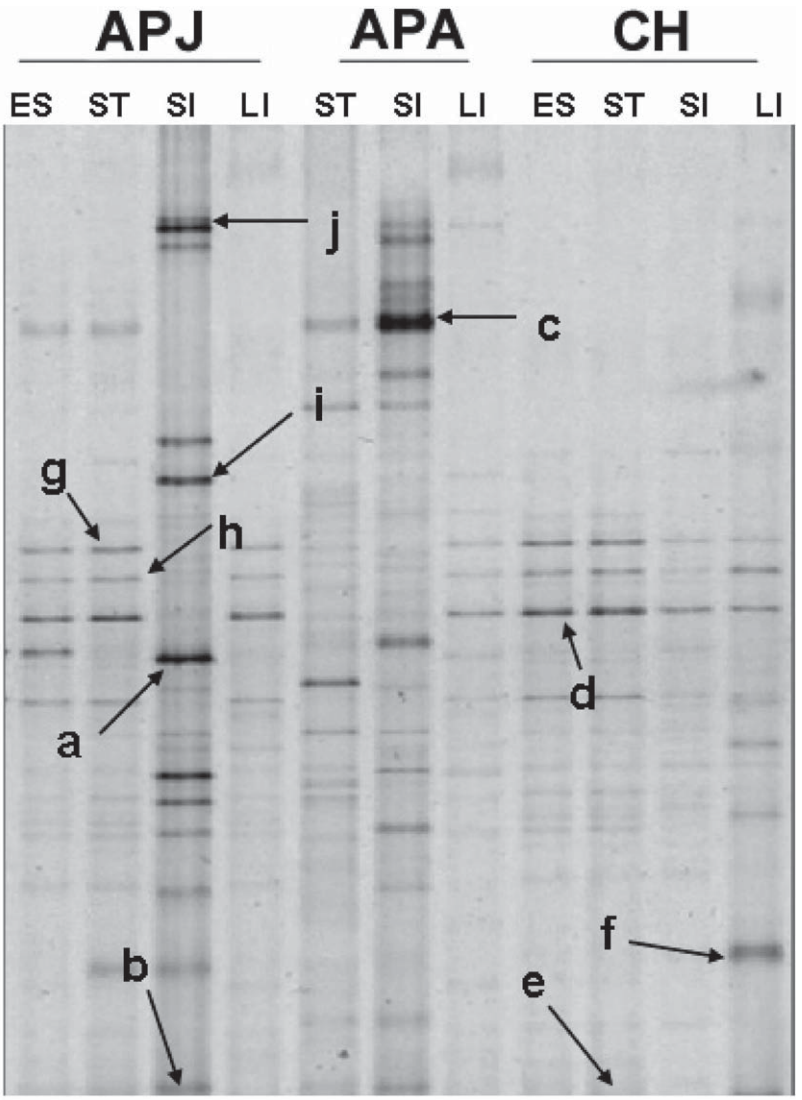

FIG. 1. DGGE gel electrophoresis band patterns of bacteria samples isolated from organs of the gastrointestinal tract of a juvenile *Agkistrodon piscivorus* (APJ), an adult *A. piscivorus* (APA), and an adult *Crotalus horridus* (CH). ES = esophagus; ST = stomach; SI = small intestine; LI = large intestine. Lettered bands were excised, sequenced, and identified to the most closely related bacterial taxa using GenBank. a) *Parabacteroides* sp., b) *Fusobacterium* sp., c) *Bacteroides* sp., d) *Lactobacillus fermentum*, e) *Lactobacillus lactis*, f) Firmicutes, g) *Lactobacillus* sp., h) *Lactobacillus hammesii*, i) *Bacteroides* sp., j) *Bacteroides fragilis*.

TABLE 1. List of bacterial taxa identified from gastrointestinal tract organs of snakes. Juvenile *Agkistrodon piscivorus* (APJ), adult *A. piscivorus* (APA), and adult *Crotalus horridus* (CH). ES – esophagus, ST – stomach, SI – small intestine, LI – large intestine. * – Digesta present in the organ. X – Bacterial taxa present. Total bands refers to the number of bands in the gel from each sample.

Bacterial Taxa	APJ-ES	APJ-ST	APJ-SI*	APJ-LI	APA-ST*	APA-SI*	APA-LI*	CH-ES	CH-ST	CH-SI	CH-LI

can be compared to known sequences of bacterial taxa which are published in the GenBank database to identify bacteria (Altschul et al. 1990). The number of bands from a sample provides a close estimate of the number of bacterial species in the sample but may not directly correspond to the number of bacteria species present (Nübel et al. 1996; von Wintzingerode et al. 1997) and bacteria present in low numbers may not be detected by PCR/DGGE (Muyzer et al. 1993).

To the best of our knowledge, no published studies have utilized PCR/DGGE to determine the bacterial diversity in the GIT of any reptile. The objective of this research was to determine the usefulness of PCR/DGGE for determining the bacterial diversity of snake GITs. We used PCR/DGGE to analyze samples from different organs in the GIT of two species of viperid snake and sequenced electrophoretic bands to identify some of the bacterial species present. Our results provide the first data on bacterial species diversity of reptilian stomachs and small intestines.

Materials and Methods.—One Timber Rattlesnake (*Crotalus horridus*) and two Western Cottonmouths (*Agkistrodon piscivorus leucostoma*) were captured opportunistically in Madison County, Arkansas in August and October of 2006, respectively. Specimens were held in captivity for less than 24 h, euthanized, measured for snout–vent length (SVL), total length (TL), weighed using an electronic balance, and dissected. During dissection, tissue from the esophagus, stomach, small intestine, and large intestine was removed, placed in sterile plastic bags, and frozen at -80°C. The esophagus was not sampled from the adult *A. piscivorus* due to financial limitations.

We used a QIAamp DNA stool mini kit (Qiagen, Valencia, CA) to extract bacterial DNA from 180–220 mg of tissue from the mucosa of the dissected gastrointestinal tract samples. The V2–V3 region of the 16s rRNA gene, corresponding to positions 339–539 of the *Eschericia coli* genome, was amplified by PCR using previously published primers (Fasoli et al. 2003; Johansen et al. 2006) and reaction conditions (Hume et al. 2003). Electrophoresis and gel staining were carried out according to the protocol of Johansen et al. (2006). Gels were viewed under UV transillumination and total number of bands and band comparison among electrophoretic lanes were analyzed using Quantity One gel analysis software (Bio-Rad, Richmond, California).

Twenty-five of the most brightly stained bands were excised from the gel for sequencing. Excised gel fragments were disrupted by forcing gel through a pin hole in the bottom of a 0.5 ml microcentrifuge tube, centrifuged at 14,000 rpm for 5 minutes, and collected in a 1.7 ml microcentrifuge tube. Disrupted gels were suspended in 300 µl of TE buffer, vortexed, and incubated at 65°C for 15 minutes. Contents were filtered through a 0.2µm filter (Pall Life Sciences, East Hills, New York) and the filtrate was mixed with 1333 µl of NH_4OAc in EtOH (10% vol/vol 7.5M NH_4OAc; 90% EtOH) and 1 µl of glycogen (20mg/ml) (EMD Biosciences). The sample was vortexed and stored at -80°C for 10 minutes then centrifuged at 14,000 rpm for 15 minutes. The supernatant was discarded and the pellet washed twice in cold 70% EtOH and resuspended in 4.5 µl of TE. DNA was sequenced with the same primers as used for amplification but without the GC clamp. Sequencing was carried out on an ABI 3100 capillary analyzing system and sequences were compared with the GenBank database using the BLAST algorithm (Altschul et al. 1990).

The gastrointestinal tract profiles were compared using the Quantity One software (Bio-Rad). Similarities were compared based on the Dice similarity coefficient which uses an arithmetic determination to analyze the degree to which banding patterns are alike. Dendrograms were created based on the grouping and relatedness between samples (each lane) and the amount of relatedness is indicated by the percentage bar above each dendrogram. A chicken ceca intestinal sample was used as an out-group to root

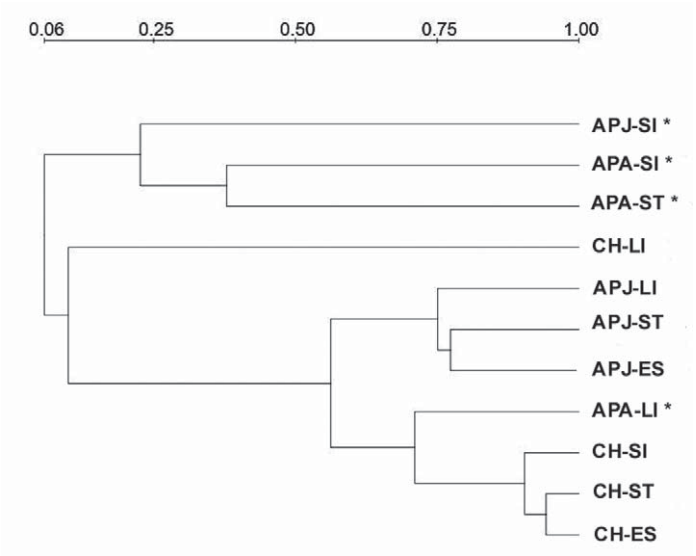

FIG. 2. A comparison of the similarity of the DGGE gel electrophoresis patterns of intestinal bacteria isolated from the esophagus (ES), stomach (ST), small intestines (SI), and large intestines (LI) of a juvenile *Agkistrodon piscivorus* (APJ), an adult *A. piscivorus* (APA), and an adult *Crotalus horridus* (CH). Relative similarity of banding pattern is indicated by the grouping on the dendrogram and the percent of similarity coefficient (bar). * - organ contained digesta.

the tree for this analysis.

Results.—Gastrointestinal tract samples were obtained from one adult female *C. horridus* (69.0 cm SVL, 73.5 cm TL, 218.6 g), one adult female *A. piscivorus* (56.2 cm SVL, 75.0 cm TL, 171.6 g), and one juvenile female *A. piscivorus* (32.0 cm SVL, 37.6 cm TL, 37.4 g). All the digestive organs of the adult *C. horridus* specimen were devoid of digesta. The stomach, small intestine, and large intestine of the adult *A. piscivorus* contained digesta. The juvenile *A. piscivorus* specimen had digesta in the small intestine and the remaining organs were devoid of digesta.

Electrophoretic gel lanes from individual snake GIT organ samples contained from 8 to 27 bands (Fig. 1, Table 1). When all GIT organ samples were combined the *C. horridus* specimen contained a total of 18 bands, the juvenile *A. piscivorus* specimen contained 57 bands, and the adult *A. piscviorus* specimen contained 46 bands. A total of 66 different bands were present from all three snakes and 12 were in common to all three specimens.

Of the 25 bands excised from the gel for sequencing, 10 were successfully sequenced and assigned to a species, genus, or higher taxa by the GenBank database using the BLAST algorithm (Fig. 1, Table 1). Insufficient DNA was present in the remaining 16 bands for sequencing. Bands identified as *Parabacteroides*, *Bacteroides*, and *Fusobacterium* were only found in *A. piscivorus* (Table 1). Bands identified as *Bacteroides* and *Fusobacterium* were found in the small intestines and stomachs of both *A. piscivorus* specimens but not in the esophagus and large intestines. *Lactobacillus fermentum* and *Lactobacillus lactis* were found in one or more organs of all three snakes (Table 1).

Similarity comparisons of the samples indicate several trends (Fig. 2). Three of the four samples which contained digesta had less than 40% homology with each other and the other samples. Most of the samples that did not contain digesta were 75% or more homologous but the *C. horridus* large intestine sample was quite unique (<10% homology). Aside from the above trends, the samples roughly grouped by individual.

Discussion.—The total number of unique electrophoretic bands observed for each of our specimens was similar to totals found in other vertebrates for which data are available. A PCR/DGGE analysis of chicken ceca found 26 bands (Hume et al. 2003). Samples from the ilea and ceca of chickens contained 17 bands (Lu et al. 2003). Rumen of steer guts showed approximately 12 bands (Simpson et al. 2002).

Lutterschmidt et al. (2007) detected nine bacterial species in the mouth and esophagus of wild *A. piscivorus* using culture based techniques. Our two esophageal samples both contained 13 bands. Our study did not identify any of the species found by Lutterschmidt et al. (2007) but we only sequenced 10 bands out of the 66 present in our samples. The nine species found by Lutterschmidt et al. (2007) might be present in our samples but were not among the bands we selected for sequencing. It is also possible the nine species found by Lutterschmidt et al. (2007) are indigenous to the oral cavity, a region we did not sample.

Variation in bacterial species diversity among our samples might be attributable to interspecific differences related to diet (Dethlefsen et al. 2007; Lutterschmidt et al. 2007), the presence or absence of digesta in the organ (Simpson et al. 2002), the developmental stage of the individual (Lu et al. 2003; Lentle et al. 2006), or the functional role and environmental conditions of the specific GIT organ (Lu et al. 2003; Wang et al. 2003). We lacked sufficient samples to test any of these possibilities statistically and future studies should be conducted to investigate these issues. We speculate that microbial diversity in our individual GIT organs was influenced by the presence or absence of digesta. Organs without digesta were generally more similar to one another than those with digesta and organs containing digesta appeared to show higher microbial diversity than those devoid of digesta (Table 1). The presence of digesta in an organ might increase microbial diversity because bacteria are introduced into the gut upon ingestion of prey or because resident bacteria, that were undetectable in empty organs, increase to detectable numbers in the presence of digesta.

All of the bacterial taxa identified from the GITs of our snake specimens are typical gut flora found in other vertebrate hosts (Lu et al. 2003; Xu and Gordon 2003; Sakamoto et al. 2007). *Lactobacillus*, *Bacteroides*, and *Fusobacterium* were among the ten genera which comprise 99% of the microbiota in human intestines (Xu and Gordon 2003). The small intestine of both *A. piscivorus* specimens contained *B. fragilis*, and an unidentified *Bacteroides* species. Bacteria in the genus *Bacteroides* affect nutrient uptake and fat accumulation in lab mice (Turnbaugh et al. 2006) and are likely to affect nutrient uptake in our snake specimens as well. All the snakes in our study were found to be carrying *Lactobacillus fermentum* and *L. lactis* in one or more organs. Because these *Lactobacilli* were found in both snake species having such different diets, they are also likely to be indigenous flora. *Lactobacilli* are common in the GIT of humans and other vertebrates and are considered health promoting or "probiotic" flora because they produce antimicrobial compounds that inhibit the growth of pathogens (Amit-Romach et al. 2004; Soomro et al. 2002). *Lactobacillus lactis* produces the antimicrobial agent nisin which is also produced commercially to prevent food spoilage (Vandenbergh 1993). Additional studies

will be required to determine the functional role of bacteria in the GIT of snakes.

Results of this study demonstrate that DGGE is a useful approach for studying bacterial diversity in snake GITs. With this tool we characterized bacterial communities present in different GIT organs of individual snakes and identified some likely indigenous species. Application of this technique to snake microbial gut ecology could provide valuable insight into the interactions of snakes with GIT bacteria and would likely increase our understanding of nutrient acquisition in snakes and other reptiles.

Alternative molecular methods for characterizing microbial communities include Terminal Restriction Fragment Length Polymorphism (T-RFLP, Osborn et al. 2000) and pyrosequencing (Liu et al. 2007; Luna et al. 2007). Both T-RFLP and DGGE have problems with PCR introduced bias but additional bias is introduced with T-RFLP because PCR products are enzymatically digested—adding significant bias towards certain products (Hartmann and Widmer 2008). Also, because T-RFLP is a fluorescence-based analysis some peaks represent artifacts and not bacteria (Hartmann and Widmer 2008). Pyrosequencing aims at identification of all bacterial species in a sample and is typically used in a clinical setting for analysis of microbial communities with minimal diversity (Luna et al. 2007). Our objective was to compare microbial communities and identify some bands of interest. Therefore, DGGE was a more appropriate and cost effective method than pyrosequencing for this study.

A number of interesting questions regarding snake GIT microbiota could be addressed using PCR/DGGE and similar techniques. For example, when snakes consume whole animal prey allochthonous microbes are introduced to their guts. How does the snake GIT cope with such an assault? Snake GITs are subject to large variations in activity level and environmental conditions. Because many snakes feed infrequently on large meals the gastrointestinal tract is upregulated during feeding and downregulated during periods of non-feeding (Secor and Diamond 1995). Does microflora contribute significantly to the increase in gut biomass which occurs during up-regulation? What happens to the GIT microflora during periods of non-feeding in the active season and during low temperature hibernation? How is the microflora reestablished when feeding ensues? How does temporal variation in the GIT microbial community influence a snake's ability to obtain energy and nutrients from its environment? Molecular techniques for the analysis of complex microbial communities will be useful tools for answering these and other important questions that will increase our understanding of how reptiles obtain energy and materials from their environments.

Acknowledgments.—We thank P. Hererra for assistance in extracting DNA and H. Voris for reviewing early versions of this manuscript. Snake specimens were collected under Arkansas Game and Fish Permit No. 080120062 issued to SJB. All animal handling procedures were approved by the Field Museum of Natural History's International Animal Care and Use Committee (Protocol Number FM06-8).

Salamanders often are considered to be the most abundant vertebrate organisms in headwater-riparian ecosystems, contributing a significant amount of biomass to ecological and ecosystem processes (Burton and Likens 1975; Davic and Welsh 2004; Peterman et al. 2008). Research has shown that salamanders can exert significant top-down limitations on ecosystem processes, acting as predators of detrivorous organisms (Davic 1983; Wyman 1998), but larval salamanders are susceptible to bottom-up limitations of leaf litter in largely allochthonous-based headwater ecosystems (Johnson and Wallace 2005). Though salamanders are thought to be integral components to fishless headwater streams, acting as predators and prey, actual quantification of their importance has been limited by accurate estimation of population sizes and densities (Bailey et al. 2004; Dodd and Dorazio 2004).

Eurycea wilderae (Blue Ridge Two-lined Salamander) is the most abundant larval species encountered in many Appalachian headwater streams (WEP, unpubl. data). Like a number of other species, two-lined salamanders exhibit a variable activity pattern (Hairston 1949; Orser and Shure 1972; Petranka 1984). During the day, larval two-lined salamanders seek refuge under rock cover or in interstitial spaces in the gravel streambed and at night move about the stream feeding (Petranka 1984). These variable activity patterns can result in drastically different measures of abundance and habitat use (Crawford 2007). Previous estimates of larval salamander abundance and density have employed a variety of techniques that include passive sampling using leaf litter bags, drift nets, or funnel traps (e.g., Bruce 1986; Waldron et al. 2003; Willson and Dorcas 2003), daytime visual encounter surveys that include lifting of cover objects (e.g., Barr and Babbitt 2001; Lowe and Bolger 2002; Smith and Grossman 2003; Welsh and Ollivier 1998), active dipnetting (Willson and Dorcas 2003), or a combination of methods (Nowakowski and Maerz, *in press*). Data collected through these various methods have been analyzed using mark-recapture techniques (Johnson and Wallace 2005; Lowe 2003), removal equations (Jung et al. 2005; Spight 1967), or using replicated counts (Dodd and Dorazio 2004).

Though there are a variety of sampling and estimation options available, researchers are often restricted by time and resources in conducting surveys. In this study, we assess two population estimation techniques: passive trapping with mark-recapture and active depletion sampling. We compare both the time and resources involved with each of these techniques and population estimates

calculated from each method.

Methods.—Surveys for larval two-lined salamanders were conducted at four headwater streams in the southern Appalachian Mountains near Highlands, North Carolina, USA during June and July of 2007. All streams were located within 5 km of Highlands, and were separated by at least 300 m. The four study sites did not differ substantially with regards to habitat characteristics, which were measured at each trap location and then averaged across all sites; values are reported as means (± SD). All four of the gravel substrate streams were fishless headwater streams (i.e., first or second order) that flowed through mixed hardwood forests. *Rhododendron* spp. dominated the understory along the stream banks. Width and depth were measured with a meter tape and ruler, and were 3.21 m (± 0.72) and 105 mm (± 9.43), respectively. Canopy cover averaged 91.9% (± 1.78) and was measured from the center of the stream using a spherical crown densiometer. The area of streambed covered by surface sedimentation averaged 28% (± 3.18) and was measured using a 0.25 m^2 sampling grid divided into 25 sections. The average elevation of study streams was 1044 m (± 151).

Passive trapping of larval salamanders was done using leaf litter traps (Nowakowski and Maerz, *in press*), which differ from leaf bags in that they are generally easier to search (WEP, pers. obs.) and they cover a greater area of stream while utilizing less material than leaf bags. Traps were constructed from 53 × 26 × 6 cm plastic plant pallets. Each trap was covered with 1.9 cm^2 garden mesh, which was held in place using 10 cm plastic cable ties on three sides. Traps were then filled with leaf litter and the fourth side was secured with a metal binder clip. Three traps were deployed at each stream, at least 5 m apart. Each trap was placed on the streambed and weighted with one or two rocks to keep it in place and tied to a secure branch or root on the stream bank to prevent loss from drift. Traps were set for ten days prior to checking to allow for colonization by invertebrates and salamanders. Leaf traps were checked once every three days for a total of four sample periods (nine days between first and last sample). Though it is possible to make population estimates after just two sampling events (e.g., Lincoln-Peterson; Lincoln 1930), three or more samples are generally recommended (Mazerolle et al. 2007) and we chose to use four sample periods for this study with the goal of obtaining more precise estimates and narrower confidence intervals.

To check for larvae, one researcher would quickly remove the leaf trap from the water and place it over a 60 × 40 × 22 cm Rubbermaid® container. Immediately after the trap was lifted from the streambed, a second researcher would use a 15 × 20 cm baitnet with <1 mm mesh to sweep directly under the trap (an area approximately 0.75 × 0.50 m). One researcher would then shake and agitate the trap over the large container while another poured approximately 35 liters of water over the trap. The resulting water and sediments were then poured from the large container through the 15 × 20 cm baitnet. The consolidated contents were then transferred into a white tray (40 × 30 × 8 cm) and sorted. Larvae were identified, counted, and given a cohort mark by clipping the tail fin at a 45° angle. All salamanders were then released at the upstream edge of the trap after it was reset. Following the fourth and final trapping period, all salamanders were released at the trap location after traps were removed from the stream.

Depletion sampling was conducted in plots centered on the area where leaf traps were previously set (i.e., three plots per site). Flags were placed in the stream bed to delineate the search area (0.75 m × 0.75 m) for depletion sampling. Depletion sampling began three days after the last trapping session. Each site was searched twice a night by two researchers (at least 45 minutes between searches) for three consecutive nights (six total samples). Sites were sampled in a different order each night to accommodate potential temporal variation in surface activity. Surface active larvae were captured using dipnets and turkey basters. No rocks or other cover objects were lifted or disturbed during depletion sampling. Following each sample, larvae were released at least 15 m downstream from the most downstream sample location. This distance effectively removed larvae from the depletion plots as most larval salamander movement occurs in the downstream direction, and movements upstream are generally less than 3 m (Johnson and Wallace 2005).

Mark-recapture data collected from trapping were analyzed using a Schumacher-Eschmeyer estimator (Seber 1982). Data from the three traps were pooled together for a single abundance estimate for each site. Abundance estimates were converted into density•m^{-2} estimates, assuming that the total area covered by each trap was 0.375 m^2 (0.75 × 0.50 m per trap). This area is greater than the trap size to account for the area searched with the dipnet. Removal data were analyzed in Program CAPTURE using Pollock and Otto's closed population estimator (Pollock and Otto, 1983) and abundance estimates were converted to density•m^{-2} estimates by dividing by the depletion plot area (0.75 × 0.75 m) .

Results.—We caught a total of 211 larvae with leaf litter traps and 237 were captured using active depletion sampling. Most of the captured larvae (93% and 92% for trapping and depletion, respectively) were smaller than 15 mm snout–vent length and are likely representative of the new cohort of two-lined salamanders, which generally have a larval period lasting about a year. The vast majority of larval captures in traps were two-lined salamanders, but traps captured a low number of larval Red Salamanders (*Pseudotriton ruber*) and larval Black-bellied Salamanders (*Desmognathus quadramaculatus*) at some sites. Density estimates could not be made using depletion sampling at Site 2 because of a lack of captures; nor could estimates be made using mark-recapture at Site 4 because of a severe storm and high water that disturbed the traps. For all other sites, density estimates calculated using mark-recapture and depletion sampling did not differ significantly (Table 1, Fig. 1). Estimates made through mark-recapture ranged from 75 larvae•m^{-2} (95% CI = 69.34–79.58) to 137 larvae•m^{-2} (95% CI = 113.87–160.80) and estimates from depletion sampling ranged from 50 larvae•m^{-2} (95% CI = 40.30–73.48) to 99 larvae•m^{-2} (95% CI = 83.83–128.43; Table 1, Fig. 1).

During the course of data collection, the time needed to complete a sample was recorded, where a sample is equal to the time needed to check three traps at a site or search three plots during depletion sampling. Both methods required about 0.50 h per site per sample period (two researchers per site per sample period; ~1 total man h; Table 2). More sample periods (six samples) were required to get estimates using depletion methods than for the mark-recapture methods (four samples; Table 2), as population estimation via depletion is dependent on reducing the population size (i.e. capturing fewer animals in each subsequent sample period). Following four sample periods, capture numbers at each site

were only reduced 55% on average, but were reduced 83% following six sample periods. As a result of our use of six sample periods, the total effort for depletion sampling was substantially greater and the cost in time per salamander was lower using depletion sampling (Table 2).

Discussion.—We successfully obtained density estimates for larval two-lined salamanders using two different closed capture techniques. In order for the results obtained from these techniques to be valid, four assumptions needed to be met: 1) the population was closed from immigration or emigration; 2) all animals had the same chance of being caught in a sample (i.e., must be a non-biased sample); 3) marking animals did not affect their catchability or survivability; and 4) animals did not lose marks between sampling periods (White et al. 1982). We are confident that these assumptions were satisfactorily met, as both studies (once started) were completed in nine days or less. The marks could not be lost over such a short time period and movement into or out of sample populations was likely minimal. Survivability and catchability are harder to estimate, but these same techniques have been used in longer term studies (WEP, unpubl. data) without apparent adverse effects on survivability.

Justifying all the assumptions of closed population models is difficult as few detailed, long-term studies of larval salamanders have been conducted. Johnson and Wallace (2005) found that only 35.7% of larvae moved more than one meter from the point of capture and the mean movement for all marked salamanders at their reference stream was 2.38 m (N = 122). These data were collected while conducting an 18-month mark-recapture study using monthly sampling. Taking the results of Johnson and Wallace (2005) into consideration, movement into or out of our seemingly confined sample plots was likely minimal.

Trapping with mark-recapture and depletion sampling provided estimates of population density that were not significantly different, though success per hour effort was about 33% less using depletion sampling. Confidence intervals and estimates for both techniques could likely be refined with the inclusion of more sample periods. Trapping and mark-recapture of larval salamanders proved to be relatively cost effective, time efficient, and required no previous experience in locating and effectively capturing salamanders. All of these are important and attractive attributes for implementing replicated studies using minimally trained personnel. One drawback to this method is the initial cost in getting materials to make and check traps. The plant pallets can be purchased from plant nurseries for ~ US $0.40 each, while garden mesh can be purchased from the hardware store in bulk (65 m^2) for ~$30.00. The Rubbermaid® container, white sorting tray, and dipnet cost an additional $18.00. Also, it is difficult to quantify the extra time involved with having to set traps and waiting to check them (10 days in this study).

Nighttime depletion sampling required only a dipnet, a turkey baster (~$10.00 total) and a headlamp, but there is a significant amount of researcher effort and experience required, which are also hard to objectively quantify. In

TABLE 1. Reported larval *Eurycea* densities from fishless 1st and 2nd order headwater streams. Passive Trapping (PT) with leaf litter traps, Area Constrained Dipnetting (ACD), Area Constrained (AC) searches, and Time Constrained (TC) searches have been used to estimate population sizes using Counts, Mark-Recapture (M-R), and Depletion estimation methods.

Species	Larvae•m-2	95% CI	Capture Method	Est. Method	Site Characteristics	Location	Reference

[b] Estimates from fishless streams only.
[c] Study included nutrient manipulations of streams; the reported value is from the unaltered reference site.

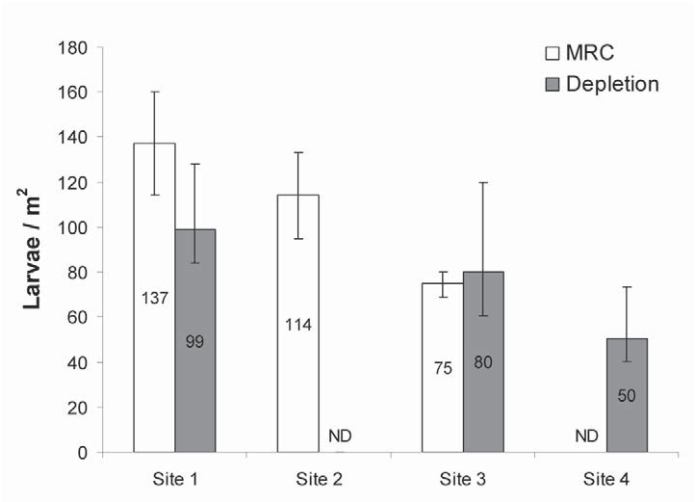

FIG. 1. Estimated larval density and 95% confidence intervals for the four study sites and the two estimation methods. No data were available to make estimates at Sites 2 and 4 using depletion and mark-recapture sampling, respectively.

order to get accurate estimates from depletion sampling, sample sizes need to show a steady, progressive decline over time (White et al. 1982), which can be variable depending on weather conditions, stream conditions, or time of sample period (Barr and Babbitt 2002; Hairston 1949; Orser and Shure 1972; WEP, pers. obs.). After four sample periods in this study, capture numbers were only 55% lower than the first sample, but decreased 83% after the sixth sample.

Estimated densities for larval salamanders are rare in the literature. Previous density estimates for larvae of the *Eurycea bislineata* complex have varied substantially with nearly all studies reporting densities less than 5 larvae•m^{-2} (Table 1). The lone exception to this is the study of Nowakowski and Maerz (*in press*), on which our leaf trapping methodologies were based. It is hard to determine whether this variation is attributable to geography, species, or the quality of habitat. Some likely factors contributing to the variable density estimates include the area of stream surveyed (i.e., selected quadrats vs. entire pools or reaches), the presence of fish or other predators, and whether or not surveys were conducted during the day or night (e.g., Barr and Babbit 2002; Burton and Likens 1975; Johnson and Wallace 2005). The costs in time and effort among the different studies listed in Table 1 are difficult to quantify, but search time would largely be affected by the complexity and amount of suitable, searchable habitat. In order to gain a greater understanding of how larval densities differ among species and regions, standardized sampling needs to be conducted. We have shown that *E. wilderae* densities in North Carolina are comparable to *E. cirrigera* densities in Georgia using similar techniques. Future research on *E. bisleanata* in northern regions utilizing leaf traps and area constrained dipnetting may provide clarity to the question of larval density in headwater streams as well as explain or alleviate the variability in density estimates currently in the literature.

Our estimates of 75 (95% CI = 69.34–79.58) to 137 (95% CI = 113.87–160.80) *E. wilderae*•m^{-2} using passive trapping are among the highest reported, and support claims that salamanders are likely important and influential organisms in headwater streams (Burton and Likens 1975; Davic and Welsh 2004; Peterman et al. 2008). Though high in comparison to previous studies, we feel our density estimates are describing the three-dimensional nature of headwater streams. As suggested by Ward (1989), there are four dimensions to lotic systems: the lateral, longitudinal, vertical, and time dimensions, and it is the vertical dimension within streambed interstices that larval salamanders often inhabit. It is widely understood that terrestrial salamanders are fossorial in nature, and Petranka and Murray (2001) demonstrated that only a small fraction of the population is surface active at any point in time, thus requiring several successive sample periods to adequately deplete population numbers. Similarly, only a fraction of the larval salamanders were surface active or inhabiting our traps during a given sample period, and only with repeated sampling and marking of animals could accurate estimates be made.

The importance of salamanders to headwater stream communities is becoming more evident (Peterman et al. 2008), further reinforcing their ecological importance (Davic and Welsh 2004). From the results of our study, we suggest that larval salamanders can be effectively sampled passively using either a leaf litter trapping technique with mark-recapture or by active depletion sampling, but there are costs and benefits to both. The quality and resolution of the subsequent results are largely dependent upon the number of sample periods used. Here we have demonstrated that four sample periods can be sufficient to get estimates using simple cohort marking and Schumacher-Eschmeyer estimation methods, while six sample periods were sufficient for removal sampling. The number of samples needed is likely to vary, depending on several factors and may be more or less dependent on one's study design and research objectives, but we feel that there is much less variability involved with trapping, allowing for a more equitable comparison among study sites. With refined sampling techniques and estimation capabilities, future research should address ecological and ecosystem processes that include both larval and adult salamanders.

TABLE 2. Estimated effort involved with each sampling method. The mark-recapture study was concluded after four sample periods; depletion was concluded after six sample periods. Time per sample is the time needed for two researchers to search three traps or three depletion plots at a single site; time per site is the cumulative time needed to sample a site (time per sample x number of samples); total effort is the cumulative time needed to collect data for abundance estimates at four sites (time per site x number of sites); and salamanders per hour are the total number of salamanders that were captured divided by the hours of total effort.

Method	Time per sample (h)	Time per site (h)	Total Effort (h)	Salamanders/h
Mark-recapture	0.48	1.92	7.68	27.47
Depletion	0.54	3.24	12.96	18.29

Acknowledgments.—We thank J. Crawford, L. Eggert, C. Rabeni, R. Semlitsch, M. Mahoney, and three anonymous reviewers for constructive comments and criticism on this manuscript. We also thank J. Costa, L. Davis, and the staff of Highlands Biological Station for use of facilities. Materials and discussions were provided by J. Maerz and J. Milanovich. A special thanks to J. Crawford and J. Wisdom for assistance with field data collections. This research was partially funded by a Highlands Biological Station Fellowship (WEP) and a cooperative agreement with the United States Forest Service Southern Research Station (WEP). This research was conducted under a U.S. Forest Service permit (HIG6493) and animal care protocol 3951 approved by the University of Missouri Animal Care and Use Committee.

Amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) presence in anurans is well documented, both nationally and globally, resulting in population declines and/or extinctions (Berger et al. 1998; Carnaval et al. 2006; Garner et al. 2005; Lips et al. 2006; Skerratt et al. 2007). Recent increased *Bd* sampling in North American wild amphibian populations has resulted in its documentation in numerous species and demonstrated its widespread geographic distribution (Adams et al. 2007; Briggler et al. 2007a; Longcore et al. 2007; Ouellet et al. 2005; Pearl et al. 2007; Reeves and Green 2006). When compared to anurans, reports of *Bd* in populations of North American caudates are limited. In North America, the presence of *Bd* has previously been reported in ambystomatids in Arizona, California, and Canada (Davidson et al. 2003; Ouellet et al. 2005; Padgett-Flohr and Longcore 2005), salamandrids in California and Canada (Ouellet et al. 2005; Padgett-Flohr and Longcore 2007) and cryptobranchids in Missouri (Briggler et al. 2007a).

In Missouri and Arkansas, *Cryptobranchus alleganiensis alleganiensis* (Eastern Hellbender) and *C. a. bishopi* (Ozark Hellbender) have experienced severe population declines (Wheeler et al. 2003). Causes of Hellbender decline are mainly linked to habitat degradation or alteration, chemical contaminants, introduced species, commercial exploitation, and diseases and pathogens, such as *Bd* (Briggler et al. 2007b). These large, aquatic salamanders live in cold, spring-fed rivers and streams in the Ozark Highlands of Missouri and Arkansas (Nickerson and Mays 1973) that provide ideal conditions for supporting *Bd* (Piotrowski et al. 2004). *Bd* was first reported in *C. a. bishopi* from the North Fork of the White River, Ozark County, Missouri (Briggler et al. 2007a). This initial detection of *Bd* in conjunction with known Hellbender population declines and optimal conditions for supporting *Bd* in other Ozark rivers prompted us to sample additional

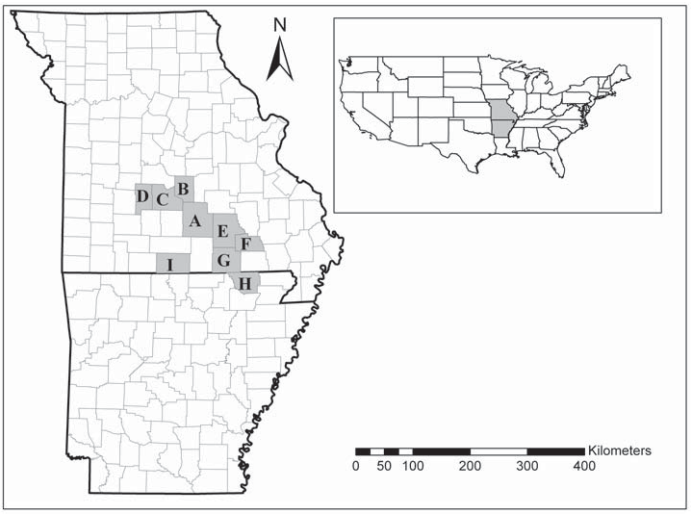

FIG. 1. Counties where *Cryptobranchus alleganiensis alleganiensis* (Areas A, B, C, and D) and *C. a. bishopi* (Areas E, F, G, H, and I) tested positive for *Batrachochytrium dendrobatidis* in Missouri and Arkansas, USA.

Hellbender populations. Herein, we report additional distribution records of Bd in wild Hellbender populations in the Ozark Highlands of Missouri and Arkansas. Both subspecies are listed as critically imperiled in Arkansas and Missouri, and state endangered in Missouri. In addition, *C. a. bishopi* is a candidate for federal listing under the U.S. Endangered Species Act (NatureServe 2008). Because of the sensitive nature of this declining species we do not provide specific locations or sample sizes, and thus, only report to the river system level within each county.

Hellbenders captured during annual surveys in 2006 and 2007 were tested for *Bd* by swabbing with a cotton-tipped wooden shaft applicator over the ventral surface of each foot, the belly, and around the thigh and vent area. Both the cotton swab end and the posterior wooden tip end of the swab were rubbed back and forth over each of these regions approximately 10 times. The wooden tip end was used to better scrape the skin layer. Once collected, the two ends of the swab were cut or broken off the applicator and placed in a 2.0-ml screw-cap tube with 1 ml of 70% ethanol and shipped to Pisces Molecular, Boulder, Colorado, for PCR (polymerase chain reaction) assay.

Positive *Bd* test results were detected in five rivers in nine counties in Missouri and Arkansas (Fig. 1; Table 1). *Bd* was detected in *C. a. alleganiensis* in the Big Piney and Niangua Rivers in four counties and in *C. a. bishopi* in five counties in the Current River, Eleven Point River, and North Fork of the White River (Table 1). Both male and female *C. alleganiensis* tested positive for *Bd*. *Cryptobranchus a. alleganiensis* had an average (± SD) total length of 47.9 ± 3.7 cm, snout–vent length of 31.9 ± 2.9 cm, and mass of 778.8 ± 151.5 g compared to an average (± SD) total length of 43.3 ± 2.0 cm, snout–vent length of 29.5 ± 1.4 cm, and mass of 528.0 ± 81.6 g for *C. a. bishopi* (Table 1).

Our results not only document the first report of *Bd* in *C. a. alleganiensis* but also show that *Bd* is geographically widespread in *C. alleganiensis* in the Ozark Highlands. With the decline of *C. alleganiensis* throughout most of its range, further sampling for *Bd* to determine the geographic extent and prevalence of this pathogen in wild Hellbender populations is warranted. Addition-

TABLE 1. Locations and associated Hellbender data where *Cryptobranchus alleganiensis alleganiensis* and *C. a. bishopi* tested positive for *Batrachochytrium dendrobatidis* in Missouri and Arkansas, USA. County designations correspond to Fig. 1. TL = total length; SVL = snout–vent length.

County Designation	County, State	River Name	Subspecies	Date	Gender	TL (cm)	SVL (cm)	Mass (g)
A	Texas, MO	Big Piney	*C. a. alleganiensis*	22 May 07	Male	46.0	30.5	867
B	Pulaski, MO	Big Piney	*C. a. alleganiensis*	15 Oct. 07	Female	52.5	34.5	932
C	Laclede, MO	Niangua	*C. a. alleganiensis*	19 Sept. 07	Male	44.0	28.5	593
D	Dallas, MO	Niangua	*C. a. alleganiensis*	23 Oct. 07	Female	49.0	34.0	723
E	Shannon, MO	Current	*C. a. bishopi*	25 Sept. 07	Female	44.5	30.5	544
F	Carter, MO	Current	*C. a. bishopi*	29 June 06	Unknown	45.0	30.0	638
G	Oregon, MO	Eleven Point	*C. a. bishopi*	31 Aug. 06	Male	41.0	28.0	455
H	Randolph, AR	Eleven Point	*C. a. bishopi*	20 Aug. 07	Male	41.5	28.0	440
I	Ozark, MO	North Fork	*C. a. bishopi*	17 Aug. 06	Male	45.0	31.0	563

ally, further research is needed to understand the effects *Bd* may have on these animals, and whether or not its occurrence has bearing on recent population declines.

Acknowledgments.—This work was funded by the Missouri Department of Conservation, U.S. Forest Service, and Ron Goellner Center for Hellbender Conservation, St. Louis Zoo. We thank J. Wood from Pisces Molecular, Boulder, Colorado, for analyzing swab samples. We also thank J. Ackerson, J. Burns, J. Civiello, S. Crain, J. Ettling, C. Fuller, J. Goss, K. Hedgpeth, R. Junge, J. Amphibian population declines driven by chytridiomycosis, a fungal disease caused by *Batrachochytrium dendrobatidis* (*Bd*), have become a major concern worldwide (Berger et al. 1999; Lips et al. 2006). Although there is evidence that not all reported amphibian declines were caused by *Bd* (Daszak et al. 2005), the disease chytridiomycosis has been linked to species declines and extinctions on several continents (Lips et al. 2006; Mendelson et al. 2006; Schloegel et al. 2006; Weldon and du Preez 2004). Ecological niche modeling based on point distribution data of *Bd* predicts it to be widely distributed, occurring under a wide variety of temperature and precipitation regimes (see figures 1–2, Ron 2005, for details). The Brazilian Atlantic rainforest was listed as one of the most suitable areas in the Neotropics for the occurrence of *Bd* (Ron 2005).

In Brazil, most amphibian population declines have been reported in the Atlantic rainforest of southeastern Brazil (Eterovick et al. 2005; Guix et al. 1998; Heyer et al. 1988; Weygoldt 1989) and, more recently, in the Cerrado at Serra do Cipó (Eterovick et al. 2005). In the Atlantic rainforest, *Bd* appears to be widely distributed, as it has been detected in histological samples of several frog species, from Rio Grande do Sul (southernmost state) to Pernambuco (northeastern) (Carnaval et al. 2006; Toledo et al. 2006a, b). However, there is not sufficient evidence linking this pathogen to population declines in this region.

Melanophryniscus moreirae is a small bufonid (mean SVL < 20 mm) found above 1800 m on the Mantiqueira mountain range (Itatiaia Plateau) in southeast Brazil (Bokerman 1967; Marques et al. 2006; Weber et al. 2007) (Fig. 1). Guix et al. (1998) reported population declines for this species although no systematic monitoring has ever been conducted. Previous histological screenings of species from several localities showed *Bd* to be widely distributed in the Atlantic Rainforest of eastern Brazil, including the Itatiaia/ Mantiqueira mountain chain (Carnaval et al. 2006; Toledo et al. 2006a, b). Considering that histology is less precise than molecular techniques such as real-time PCR in the detection of *Bd* (Boyle et al. 2004; Hyatt et al. 2007; Kriger et al. 2006), the number of positive cases found by Carnaval et al. (2006) and Toledo et al. (2006a, b) might be underestimated. We examined *M. moreirae* for the presence of *Bd* using PCR assays.

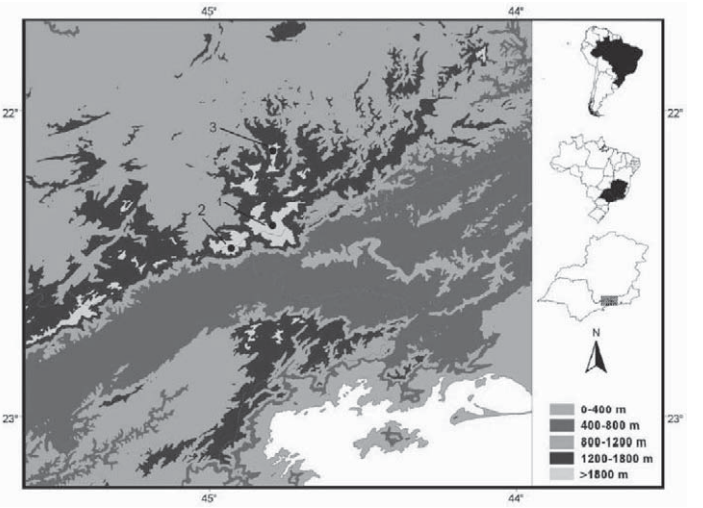

FIG. 1. Distribution of *Melanophryniscus moreirae* in southeastern Brazil, in the Itatiaia Plateau municipalities: 1) Itamonte/ MG; 2) Queluz/ SP; and 3) Aiuruoca/ MG (modified from Weber et al. 2007).

Methods.—The study was conducted along the Rio Campo Belo Valley in the Itatiaia National Park (22.27ºS, 44.57ºW to 22.46ºS, 44.7ºW), within the states of Rio de Janeiro, Sao Paulo, and Minas Gerais. This is a mountainous region with high plateau vegetation characterized by humid subalpine grasslands ("campos de altitude") (Safford 1999).

In 2006, 50 adult male *Melanophryniscus moreirae* were captured during October–November, when toads were breeding in shallow puddles (Bokerman 1967; Guido-Castro 2006; Starrett 1967). Toads were captured in individual plastic bags and measured for snout–urostyle length (± 0.1 mm). A swab was run ten times over the body's ventral surface, the sides—from groin to armpit, and the thigh's ventral surface (Kriger et al. 2006). Additionally, we performed five outward strokes on the undersides of each toad's feet. Swabs were initially stored in ice, and within 24 h transferred to -19.0°C. Toads were marked by toe-clipping to avoid resampling.

We analyzed swabs using quantitative (real-time) PCR techniques in a single assay: all 50 samples plus a set of four standards and three negative controls were run on a single plate. Subsequently, positive samples were run in triplicate assays with a new set of standards and controls (Boyle et al. 2004; Kriger et al. 2006). DNA was extracted from swabs using Prepman™ Ultra (Applied Biosystems, California) according to manufacturer instructions as previously described (Boyle et al. 2004). Real-time Taqman PCR assays were performed using an Applied Biosystems Prism 7000 Sequence Detection System according to Boyle et al. (2004). We classified each sample as positive or negative for infection with *Bd*. We used the number of *Bd* zoospores present on the swab as a measurement of toad's intensity of infection. The concentration of each sample was estimated by comparison with a standard curve of the four serial dilution points (100, 10, 1, and 0.1) of *Bd*-zoospore equivalents. Our estimate of the number of zoospores in infected individuals was given by the mean value of *Bd e*quivalents detected in the PCR assay run in triplicate based on the standard curve.

Results.— Of 50 adult males examined, only two (4%) were in-

fected with *Bd* (SUL = 24.9 mm and 26.1 mm). One was collected on 23 October (22.37°S, 44.7°W) and the other on 23 November 2006 (22.37°S, 44.41°W). The numbers of zoospore equivalents were low (14 and 15 zoospore equivalents). No evident clinical or abnormal signs were observed in these toads.

Discussion.—This is the first report of *Bd* in *M. moreirae* and the first for the genus. Even though the prevalence and the severity of infection were low, these results suggest precautionary measures should be taken considering the restricted geographic range of *M. moreirae*.

Our work adds to the few other studies of *Bd* infection in Brazilian anurans (Carnaval et al. 2006; Toledo et al. 2006a, b). However, few inferences on the epidemiological status of the fungus in Brazilian anuran communities can be made because very little information is available. At this point, we have no data on the impact *Bd* might have on individual toads, populations, or communities in the studied area. We found no indication that the toads we sampled showed symptoms of the disease. There have been reported cases of *Bd* presence with no apparent impact on infected populations (e.g., Retallick et al. 2004) and reservoir hosts are known for many diseases. In general, whenever a species is considered to be the reservoir host for a given pathogen, its prevalence of infection is maintained at high rates, once the pathogen has little or no effect on the reservoir species (McCallum and Dobson 1995). The prevalence of 4% found here was rather low. Monitoring of *M. moreirae* should contribute to our current understanding of the dynamics of this disease and to determine and try to avoid possible impacts of *Bd* on this endemic species.

Acknowledgments.— We thank CNPq and Biodiversitas for funding. D. Boyle from CSIRO, Australia, provided the DNA standards. Instituto Biomas made several facilities available. We appreciate the financial support provided by RANA for one of the authors (TKF) to attend the workshop on chytrid investigation. The study was undertaken under RAN/IBAMA permit No. 02629,000152/06-54. FRL was supported by a doctorate CNPq fellowship. MVS received a research fellowship from CNPq (301401/2004-7).

To date, few surveys for the presence of the fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*) have been conducted or published on amphibian populations in the southeastern United States (Daszak et al. 2005; Green and Dodd 2007). This may be due in part to a lack of concern because amphibian mass mortalities attributable to *Bd* have not been reported. Georgia hosts one of the country's richest and most diverse amphibian faunas, including 55 described species of salamanders and 31 species of frogs (Jensen et al. 2008). The goal of this study was to conduct a baseline survey for *Bd* in a large number of amphibian taxa in a variety of physiographic regions and ecosystems in Georgia.

From June 2006 to June 2008, we captured and swabbed adult amphibians of as many species as we could locate in each of the five major physiographic regions in Georgia (Cumberland Plateau, Ridge and Valley, Blue Ridge, Piedmont, and Coastal Plain; Wharton 1978). Survey methods included visual encounter surveys and road cruising, both of which were conducted in conjunction with other research (Graham 2007; Graham et al. 2007). We swabbed each amphibian captured per Brem et al. (2007) and samples were analyzed via PCR by one of two laboratories (Veterinary Pathology Laboratory of M. Levy, North Carolina State University; Wildlife Disease Laboratory of A. Pessier, Zoological Society of San Diego, CA).

Bd-specific real-time Taqman (Applied Biosystems, Foster City, CA) PCR was performed according to the method of Boyle et al. (2004). Briefly, dried swabs were processed by adding 30–40 mg of 1.0 mm glass beads (Research Products International Corp, Mt. Prospect, IL) and 100 µl Prepman Ultra (Applied Biosystems, Foster City, CA) and processed for 1 min in a Mini Beadbeater (Biospec Products, Bartlesville, OK) at 5000 rpm. Following 10 min in a boiling water bath the tubes were cooled for 2 min at room temperature and centrifuged at 13,000 rpm in a Marathon 16km centrifuge (Fisher Scientific, Pittsburg, PA). Twenty microliters (µl) of liquid was removed, used immediately or stored at 4°C for later analysis. One µl of this mixture was used as template for the PCR assay. Positive controls consisted of *Bd* isolate 197 (Longcore et al. 1999) cultured on 1% tryptone agar at 23–25°C, and negative controls consisted of deionized water and/or pond water from a *Bd*-free site.

Our results offer baseline information regarding the presence and prevalence of *Bd* in Georgia (Fig. 1). In terms of number of species (N = 47) and geographic scope (> 400 km and 43 localities), to our knowledge this study represents one of the most comprehensive surveys to date for *Bd* in eastern North America. We sampled 10 of the 12 families (83%) of amphibians in Georgia, including 18 of 22 genera (82%) and 47 of 86 species (55%) (Table 1). Of 533 samples taken from amphibians throughout the state from June 2006 to June 2008, 10 were *Bd*-positive, suggesting a low overall prevalence (1.88%). Eight of these positive results were taken from three Green Frogs (*Rana clamitans*), three Pickerel Frogs (*R. palustris*) and two Spotted Dusky Salamanders (*Desmognathus conanti)* from the same site (Crockford-Pigeon Mountain WMA) located on Pigeon Mountain in the Cumberland Plateau of northwest Georgia (34.7100°N, 85.3750°W) on 27 July 2006. Pigeon Mountain is an ecologically unique area of Georgia, thus the detection of *Bd* may be cause for concern. Not only is this site and the surrounding areas home to protected amphibian species (e.g., Green Salamander, *Aneides aeneus*; Tennessee Cave Salamander, *Gyrinophilus palleucus*), it is the sole location of the endemic Pigeon Mountain Salamander (*Plethodon petraeus*). Our finding of *Bd* in the plethodontid salamander *D. conanti* heightens concern for these other plethodontids. The remaining positive samples were taken from two Southern Leopard Frogs *(R. sphenocephala*) from a site in the Coastal Plain of eastern Georgia (4.0 km N of Matthews; 33.2380°N, 82.2979°W) on 10 June 2006. All of the *Bd*-positive individuals appeared healthy and did not exhibit physical or behavioral symptoms of chytridiomycosis (Daszak et al. 1999).

Our study supports the findings from other surveys, confirming that *Bd* is present in southeastern North America (Daszak et al. 2005; Green and Dodd 2007; B. Rothermel, pers. comm.). Due to the low number of individuals from each taxon sampled, we can-

not estimate the prevalence of *Bd* for individual species. Similar to statewide *Bd* studies in the northeastern United States (Longcore et al. 2007), our survey indicates that the overall prevalence of *Bd* is low (1.88%). Hence, rigorous sampling of many individuals and many localities may be needed in some cases to detect the presence of this pathogen in certain species or areas. It is important to know the distribution of amphibian populations that contain *Bd*-positive individuals in order manage them to prevent the spread of *Bd* from the southeastern United States to other regions of the world (e.g., via fisheries or wildlife management or studies, transfer of untreated water between sites, pet and food trade), because elsewhere, chytridiomycosis is linked to population declines and extinctions.

Acknowledgments.—For field assistance, we thank A. Fusaro, L. Giovanetto, J. Jensen, B. Johnson, A. Kramer, A. Wallace and C. Old. We also thank G. Lowry and the Hambidge Arts and Science Center for allowing us access to their property. M. F. Poore of North Carolina University and A. P. Pessier of the Zoological Society of San Diego conducted all molecular analyses. R. M. Bonett and J. R. Mendelson provided valuable comments for this manuscript. Funding was provided by the Atlanta Botanical Garden.

Venezuela is among the ten most biodiverse countries in the world, particularly in terms of amphibians (IUCN et al. 2006). However, 18 amphibian species endemic to this country are critically endangered (IUCN et al. 2006; Rodríguez and Rojas-Suárez 1995); seven of these have not been observed in their natural habitats since the early 1990s despite intensive sampling efforts during the last decade (La Marca and Lötters 1997; La Marca and Reinthaler 1991; Manzanilla and La Marca 2004). Although the causes for most of these declines are not well understood, the high prevalence of the chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) in museum specimens of species collected just before their disappearance lead us to question whether chytridiomycosis was linked to the declines of some Venezuelan amphibians (Bonaccorso et al. 2003; Lampo et al. 2006b).

In Venezuela, the Cordillera de Mérida and the Cordillera de La Costa harbor most of the critically endangered species, including nine *Atelopus* species, a neotropical genus severely affected by declines (IUCN et al. 2006; La Marca et al. 2005; Lötters et al. 2004). As with other regions, most declines occurred at high altitudes in relatively pristine habitats. Other high-elevation pristine habitats where unusual mortalities of frogs were reported during the 1980s are the remote tepuis (tabletop mountains) of the Guianan Basin. This area is particularly interesting in light of hypotheses about human-mediated translocation of *Bd*, because human contact has been very limited on these tepuis (Lampo and Señaris 2006). Therefore, *Bd* should be absent from these remote and isolated areas.

To assess the risk that *Bd* represents to Venezuelan amphibian biodiversity, several studies have been conducted aiming to detect *Bd* in anuran species, identify hosts and reservoirs, quantify prevalence or identify variables affecting the prevalence and intensity of infection (Hanselmann et al. 2004; Lampo et al. 2006b; Lampo et al. 2006a; Lampo and Señaris 2006; Nicolás 2007; Rodríguez-Contreras et al. 2008; Sánchez et al. 2008). Based on these studies and one new host species reported here, we summarize the species and geographic distribution of *Bd* in Venezuela. Samples were taken from live wild frogs or museum specimens collected from three montane regions: the Cordillera de Mérida, the Cordillera de la Costa, and the Guianan tepuis (Table 1). In all these localities species have suffered declines (Bonaccorso et al. 2003; Lampo et al. 2006b; Lötters et al. 2004; Manzanilla and La Marca 2004) or unusual mortalities have been reported (Ayarzagüena et al. 1992; Gorzula and Señaris 1998). Detection of *Bd* from museum specimens was conducted using histology (Berger et al. 1999). Except for all infected bullfrogs reported in Hanselmann et al. (2004), all live specimens were diagnosed by conventional PCR (Annis et al. 2004) and real time PCR assays (rt-PCR) (Boyle et al. 2004) (Table 1). Standards for zoospore quantification in rt-PCR assays were provided by the Animal Health Laboratory (Australia). We adopted the species nomenclature published in the Amphibian Species of the World (Frost 2007) and listed the geographic coordinates for all sampling locations, except for that of *A. cruciger*. Whenever samples from a species included more than two locations, we provided the upper left and bottom right geographic coordinates for the distribution polygon (Table 1). Except for the two localities in the remote tepuis of the Guianan Basin, species with only negative records were not included; some were the result of small sample sizes and others had no geographic coordinates associated in the original publications.

In Venezuela, *Bd* has been detected in species that have suffered population crashes in the past (Bonaccorso et al. 2003), and also in many other common species showing no evidence of declines (Table 1). This pathogen appears to be widespread in amphibian communities of the Cordillera de Mérida between 8.50ºN, 71.25ºW and 8.67ºN, 71.50ºW, in altitudes from 120 to 2600 m (Fig. 1). Therein, *Bd* infects 17 species in six families found in ephemeral and permanent ponds, streams and terrestrial habitats of cloud forests or highly disturbed areas (Table 1) (Lampo et al. 2006b; Lampo et al. 2006a; Sánchez et al. 2008). Among infected species in the Cordillera de Mérida, the American Bullfrog (*Lithobates catesbeianus* [formerly *Rana catesbeiana*]) appears to be a key

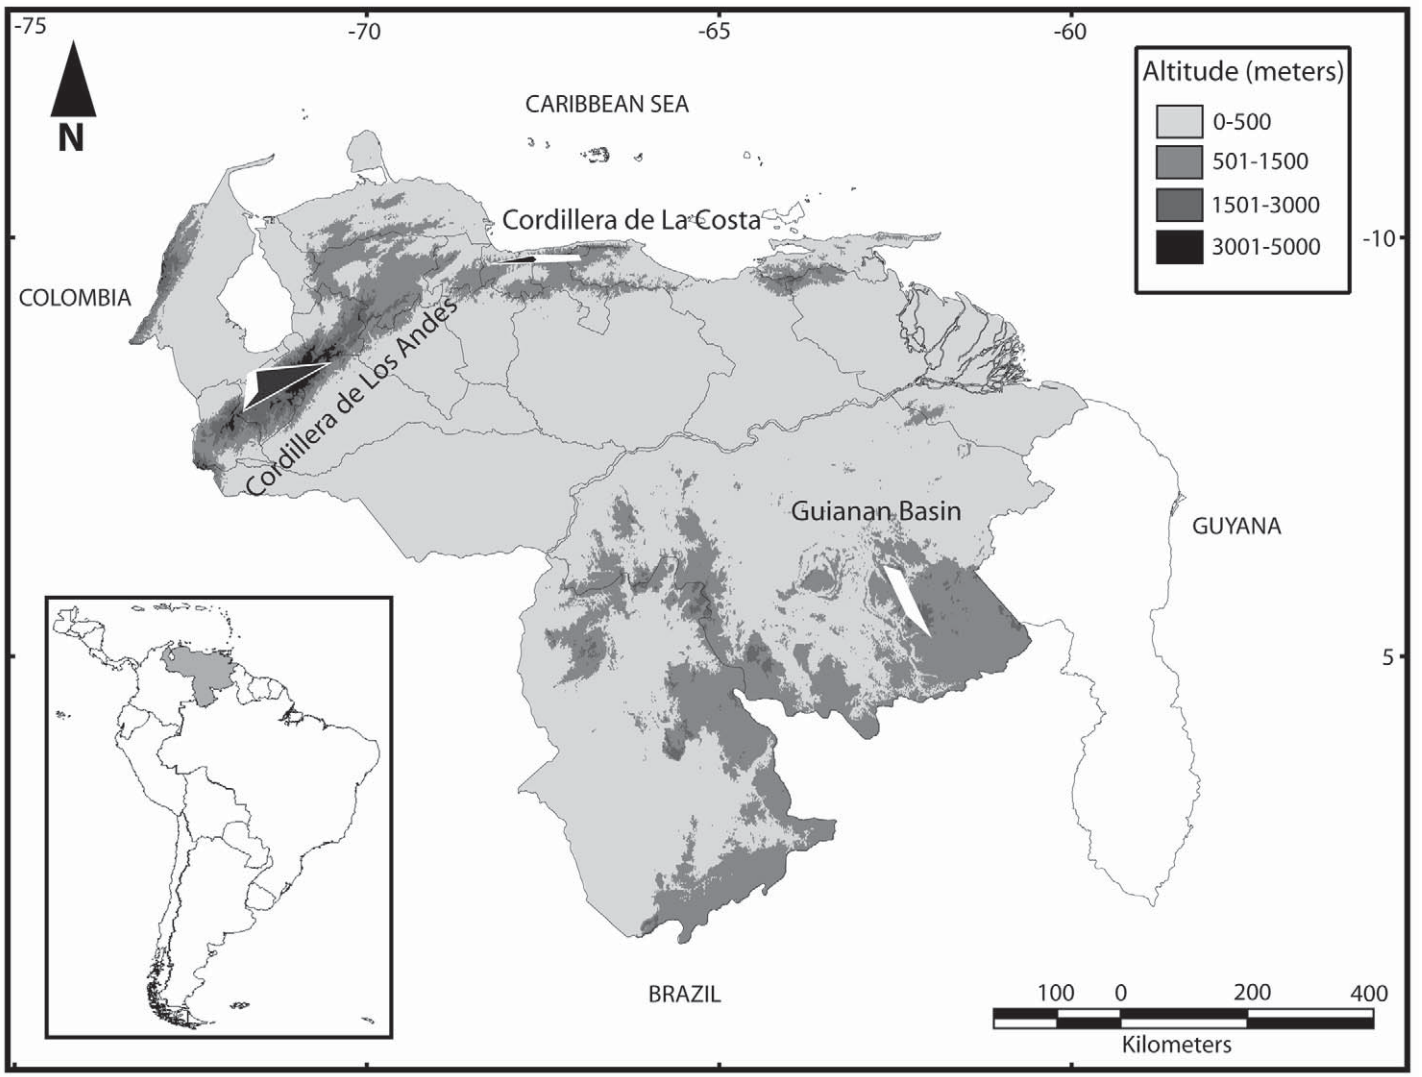

FIG. 1. Geographic distribution of the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) in Venezuela. White polygons contain all sampling locations (positive and negative) and represent the areas sampled for *Bd*. Black polygons are subsets of the white polygons that contain all positive samples and delimit the areas for which we have evidence of infection. Polygons were constructed using the minimum convex method adopted by the IUCN for determining extent of occurrence (http://www.iucnredlist.org/info/categories_criteria1994).

reservoir; it has the highest prevalence of infection (80–96%) but no apparent clinical signs (Hanselmann et al. 2004; Sánchez et al. 2008). Although *L. catesbeianus* currently occupies an area less than 50 km^2, its geographic distribution is expanding. Thus, the exposure of endemic species to *Bd* is likely to increase as bullfrogs invade new geographic areas.

Most critically endangered species of the Cordillera de Mérida have not been observed since the early 1990s. Nontheless, *Bd* appears to persist in remnant populations of some of these species. For example, it was detected in the only Andean *Atelopus* frog seen since 1994 (*Atelopus mucubajiensis*) (Lampo et al. 2006a), and in one *Aromobates meridensis*, a species with a few known populations (IUCN et al. 2006). Although it is not well understood why some species have suffered crashes while many others coexist with *Bd* with no apparent effect, increasing evidence suggests that species-specific responses (Blaustein et al. 2005; Carey et al. 2006; Daszak et al. 2004; Lampo et al. 2006a; Nichols et al. 2001) and environmental stressors are important in determining the relationship between infection and disease (Alford et al. 2007; Berger et al. 2004; Daszak et al. 2004; Di Rosa et al. 2007; Pounds et al. 2006).

In the Cordillera de la Costa, two sympatric frogs, *Atelopus cruciger* and *Mannophryne herminae*, tested positive for *Bd* (Nicolás, 2007; Rodríguez-Contreras et al. 2008) (Fig. 1; Table 1). *Atelopus cruciger* is a critically endangered species that occurs in this region whose disappearance for almost two decades was associated with *Bd* (Bonaccorso et al. 2003). Before 1986, its altitudinal distribution ranged from sea level to 2400 m, however, all recently discovered populations are located below 500 m (Rodríguez-Contreras et al. 2008). In these populations the prevalence and intensity of infection appears to be low. However, one adult male was found morbid with excessive sloughing and severe infection (244,484 zoospores in 1–3 mg of tissue) (Rodríguez-Contreras et al. 2008). This evidence suggests that *A. cruciger* could be recovering only in those locations where *Bd* growth is limited by high temperatures. *Mannophryne herminae*, on the contrary, is a widely distributed frog of the Cordillera de La Costa whose habitat overlaps extensively with that of *A. cruciger*. The presence of *Bd* in this species could affect

TABLE 1. Geographic and species distribution of the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (Bd) in Venezuela. IUCN red list categories (see http://www.iucnredlist.org/info/categories_criteria2001): CR = critically endangered; NT = Near Threatened; EN = Endangered; LC = Least Concern; VU = Vulnerable. MHNLS = Museo de Historia Natural La Salle (voucher specimen number indicated).

the dynamics of chytridiomycosis in *A. cruciger*, depending on the relative magnitude of interspecific transmission (Nicolás 2007). Therefore, *in situ* conservation efforts for *A. cruciger* must necessarily include the monitoring of *Bd* infection in *M. herminae*.

The remote highlands of the Guianan tepuis is the only area in Venezuela were unusual mortalities were reported between 1984 and 1986, but no evidence of *Bd* was found in 37 museum specimens collected during those years (Fig. 1) (Lampo and Señaris 2006). No detection of *Bd* from museum specimens from this area do not necessarily indicate the absence of the pathogen. However, the accumulation of evidence from this and other secluded areas will be important in evaluating the hypothesis of human-mediated translocation of *Bd* (Lampo and Señaris 2006).

Conserving endangered amphibian species is a major environmental challenge. Rates of extinction in the Neotropics are among the highest in the world, yet data to inform conservation efforts remain scarce. Although several factors likely contribute alone and synergistically to amphibian declines in the Neotropics (La Marca et al. 2005; La Marca and Reinthaler 1991; Lampo et al. 2006b; Pounds and Puschendorf 2004; Pounds et al. 1999; Pounds et al. 2006; Pounds and Crump 2004), amphibian chytridiomycosis appears to be a key factor (Bonaccorso et al. 2003; La Marca et al. 2005; Lampo et al. 2006b; Lips et al. 2003; Lips et al. 2005a; Lips et al. 2005b; Lips et al. 2006; Pounds et al. 2006; Pounds and Crump 2004; Puschendorf et al. 2006a; Rodríguez-Contreras et al. 2008). *Bd* also seems to be widespread among species for which there is no evidence of declines (Beard and O´Neill 2005; Kriger and Hero 2007; Nicolás, 2007; Ouellet et al. 2005; Puschendorf et al. 2006b; Sánchez et al. 2008; Woodhams and Alford 2005). A comprehensive map of pathogen distribution in relation to species declines as well as a thorough understanding of the relationship between infection and disease under different ecological and climatic scenarios are necessary before we can asses the risk associated with this emerging disease.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 39, Number 1 (March 2008).

CAUDATA — SALAMANDERS

ANEIDES AENEUS (Green Salamander). **DIGIT MORPHOLOGY.** Green Salamanders are known to have unique digits that are thought to be an adaptation to a climbing lifestyle on rock outcrops and trees (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington D.C. 587 pp.). Although the complete osteology of the genus *Aneides* shows that *A. aeneus* has a curved terminal phalanx (Wake 1963. J. Morphol. 113:77–118), no studies have been done to determine

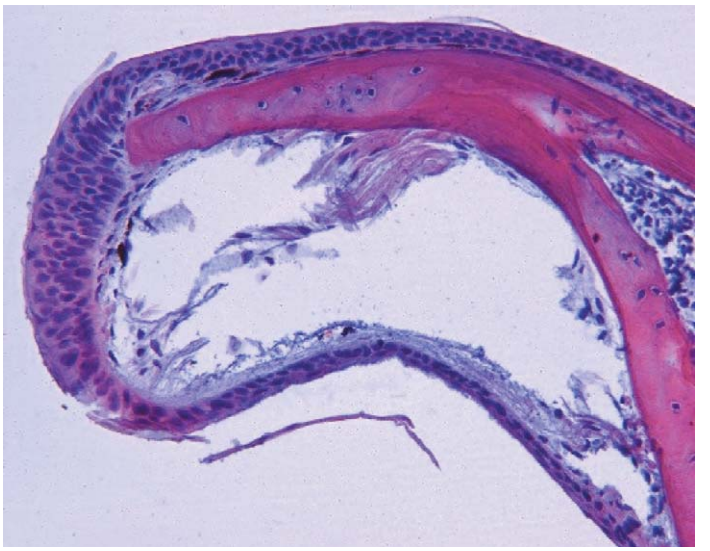

Fig. 1. Sagittal section showing terminal phalanx (TP), squamous tissue layer (Sq), and ventral position (V). 200x.

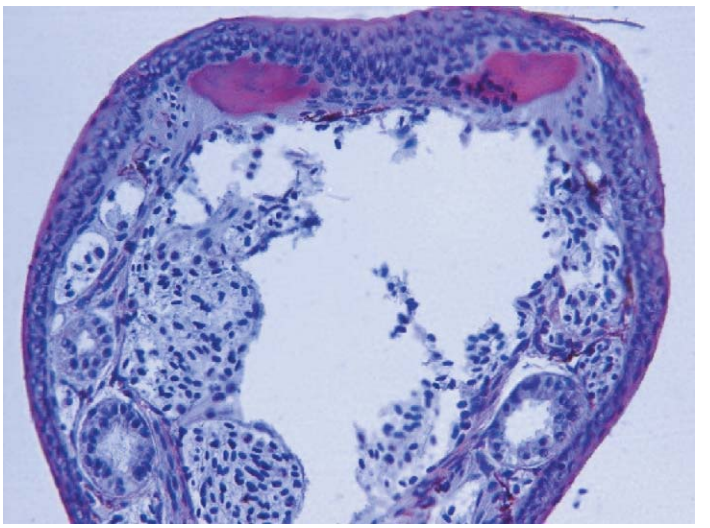

Fig. 2. Horizontal section showing doublet tips of terminal phalanx (TP), glandular cells (G), squamous tissue layer (Sq), and distal (Di) orientation. 200x.

what cellular structure(s) comprise the digits on the distal end of each digit. Here, we report the cellular morphology of the digit structure using light micrographs and stained histological preparations.

Digits (N = 60) were amputated from preserved *A. aeneus* from the West Virginia Reptile and Amphibian Museum at Marshall University. Digits were decalcified, dehydrated in ethyl alcohol and xylene, immersed in melted paraplast overnight, and embedded in fresh melted paraplast in embedding molds. Digits were oriented in molds to produce sagittal and horizontal sections. Digits were then sectioned at 10μm with a microtome and stained with hematoxylin and eosin Y.

Sagittal sections (Fig. 1) revealed an increased thickening of squamous cell layers from two cell layers at the crest of the terminal phalanx, to four or more layers thick at the tip of the terminal phalanx. This thickness remains through the distal portion of the digit tapering sharply to two cell layers thick on the ventral portion of the digit. Horizontal sections (Fig. 2) expose glandular cells lining the perimeter of the digit just underneath the squamous tissue layer. Glandular cells appear in clusters of 9–20 ovular shaped cells arranged in a spherical profile. The number of squamous cell layers was also shown to increase around the doublet tip of the distal most part of the terminal phalanx.

It is unknown how the terminal phalanx influences the climbing ability of *A. aeneus*. With the degree of dermal thickening and glandular cells associated with the terminal phalanx, it is possible that these structures act as a simple friction-based mechanism. The thick dermis and glandular structures could lend to the shape while allowing the distal portion of the digit to be flexible enough to grip irregularities on the substrate surface. It is also unknown to what extent the glandular cells secrete mucous that might aid in the adhesive capabilities of the digit, effectively allowing *A. aeneus* to cling to different substrates. To our knowledge, this is the first report disclosing the cellular morphology and possible adhesive mechanism of *A. aeneus* digits.

EURYCEA BISLINEATA (Northern Two-lined Salamander). **HABITAT USAGE.** *Eurycea bislineata* is a streamside salamander that lays eggs and passes through its larval stage in cool running waters throughout its broad range (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C., 587 pp.). In New York State, the species is abundant and widely distributed, and generally occupies the same habitats as elsewhere, with adults found along streams and in surrounding forests, and eggs and larvae occurring in lotic systems (Gibbs et al. 2007. The Amphibians and Reptiles of New York State. Oxford University Press, New York, 422 pp.). A single, startling exception is found in Lake Minnewaska, Ulster Co., New York, where adults, larvae, and eggs of this species are found within the lake to depths exceeding 10 m (Bahret 1996. J. Herpetol. 30:399–401). Herein, we report another important exception—an established population of *E. bislineata* occupying semi-permanent marl ponds in central New York State.

The salamanders live along and within a chain of ten, glacier-created kettle ponds surrounded by mixed deciduous forest and agriculture in Cortland Co., New York. The ponds range in size from 0.14 to 1.2 ha in surface area with depths to 3 m, and are separated by 10–30 m. Their substrates are calcareous and their waters clear and oligotrophic. Hydroperiods vary among the ponds and range from drying completely every year, to drying during late summer one in every four or five years, to never drying completely during the 17 years of our observation. The two streams nearest to the ponds are 1.2 and 1.6 km away and separated from the ponds by busy multi-lane roads and commercial buildings with large parking lots. Adult *E. bislineata* are abundant beneath stones and logs surrounding and within each of the ponds in the chain. The dominant vegetation in the ponds is the alga, Chara. Some or all of the ponds support populations of other salamanders (*Ambystoma jeffersonianum* complex, *A. maculatum*, *Notophthalmus viridescens*), frogs (*Bufo americanus, Pseudacris crucifer, Hyla versicolor, Rana clamitans, R. palustris, R. pipiens*, and *R. sylvatica*), and turtles (*Chelydra serpentina* and *Chrysemys picta*).

One pond (0.14 ha surface area), which dries about once every five years, was part of repeated herpetological surveys in the area over the last 17 years. We found adult *E. bislineata* each year at this pond and have captured newly metamorphosed juveniles there in five different years. Larvae have been seen in the pond in summer and fall, and captured in dip nets. Because the surveys did not include disturbing the stones deep within the ponds, eggs have not been observed.

Taken together, the high abundance of adult *E. bislineata*, the presence of many newly metamorphosed individuals, the observation of larvae, and the significant distance to the nearest lotic system, suggest that this is an isolated population of this species successfully reproducing within a series of semi-permanent marl ponds. Voucher specimens are held in Bowers Science Museum, SUNY at Cortland.

Submitted by **BRANDON WHEELER** (e-mail: Steele720@gmail.com), and **PETER K. DUCEY**, Department of Biological Sciences, State University of New York at Cortland, Cortland, New York 13045, USA.

PLETHODON GLUTINOSUS (Northern Slimy Salamander). **REFUGIA FROM DROUGHT.** *Plethodon glutinosus* is considered to be a strictly terrestrial salamander (Petranka 1998. Salamanders of the United States and Canada, Smithsonian Inst. Press, Washington, DC. 587 pp.). Rare cases exist where individuals have been removed from the stomachs of fish presumably after being washed into lotic environments by storms (Sorrell et al. 2005. Herpetol. Rev. 36:429). Under normal rainfall conditions *P. glutinosus* has been observed to occupy small (< 9 m) home ranges (Wells and Wells 1976. Herpetologica 32:156–162). Documented responses to drought include aggregating in large numbers under logs (Wells and Wells 1976, *op. cit*.) or migrating from surrounding forests into caves (Humphries 1956. Copeia 1956:122–123). It has not been previously documented that these salamanders use cover objects in dry streambeds during droughts to avoid desiccation.

The summer of 2007 was historically dry in Alabama with rainfall well below normal (National Climate Data Center 2007. [http://www.ncdc.noaa.gov/oa/ncdc.html]). On 9, 11, and 12 Sept 2007, 7 *P. glutinosus* were found under flat stones in the riffles of a first order stream. At this time epigean flow had been reduced to isolated pools leaving riffles and runs dry. This stream is located in a mixed hardwood forest of secondary growth in the Talladega National Forest (WGS 84, 33.5469°N, 85.8224°W). Searches of cover objects in the streambed were performed only during daylight hours. As the microhabitat under logs and in leaf litter on the surrounding hillsides were extremely dry it is thought that these individuals were seeking refuge from desiccation under moist rocks in the streambed. An additional individual was found drowned in an isolated stream pool that was ~ 7 cm deep. The presence of this drowned individual may attest to the terrestriality of these animals and how extreme the conditions were to force this species to move to such a perilous environment.

PSEUDOTRITON MONTANUS MONTANUS (Eastern Mud Salamander). **HABITAT USE.** Habitat use by adult *Pseudotriton montanus* has been reported as mesic habitats along rivers or swamps (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Press, Washington, D.C. 587 pp.). As part of a herpetofaunal survey of Hobcaw Barony in Georgetown County, South Carolina, I set up a plus-shaped drift fence array in Longleaf Pine (*Pinus palustris*)/ Turkey Oak (*Quercus laevis*) habitat at WGS 84 33.30682°N, 79.26372°W. The drift fence array was made of silt fencing with each arm ca. 16.5 m in length and four funnel traps along each of the four arms. On 10 May 2007 two adult *P. m. montanus* were found in the funnel traps. The previous evening 39.6 mm of rain fell at nearby Georgetown, 7.5 km NNW of Hobcaw Barony (www.wunderground.com/weatherstation/WXDailyHistory.asp) and there was evidence of precipitation at the trapping site. This is the first report that I am aware of *P. m. montanus* using a xeric habitat. One of the specimens (JDC-2137) will be deposited in the Charleston Museum, Charleston, South Carolina, USA.

I thank the Belle W. Baruch Foundation for funding the survey access to the study site.

Submitted by **JEFFREY D. CAMPER**, Department of Biology, Francis Marion University, Florence, South Carolina 29506, USA; e-mail: jcampte@fmarion.edu.

RHYACOTRITON KEZERI (Columbia Torrent Salamander). **LARVAL DIET.** Bury and Martin (1967. Copeia 1967:487) reported on the stomach contents of 36 post-metamorphic *R. variegatus* from northwestern California, the only diet study for any species of *Rhyacotriton*. Data on larval diet are lacking entirely. Herein, we report on larval diet for *R. kezeri*.

TLH made one observation in a small (< 2 m wide), 2nd-order (Strahler 1952. Geol. Soc. Am. Bull. 63:923–938) tributary of Minnie Creek, off the South Fork Willapa River, Willapa Hills, southwestern Washington State, USA (WGS 84, 46.580°N, 123.726°W, elev. 224 m). This site was in 2nd-growth forest managed for timber by the Washington Department of Natural Resources (WDNR). Western Hemlock (*Tsuga heterophylla*) with interspersed Western Red Cedar (*Thuja plicata*) dominate the overstory; Sword Fern (*Polystichum munitum*) is prominent in the understory.

At 1549 h on 9 July 2007, during measurement of a larval *R. kezeri* (31 mm SVL, 18 mm tail) in a clear polyethylene bag partly filled with water, TLH observed the animal regurgitate two *Neodiprion* sawfly larvae. The larvae were immediately preserved in 95% ethanol for subsequent examination. The *R. kezeri* had been found in sand beneath a 10 cm cobble in a riffle in the non-fish-bearing portion of the stream (126 m above the point where the last fish was recorded).

Both sawfly larvae had a narrow (1 mm wide) pale mid-dorsal stripe and one dark stripe (2 mm wide) running dorsolaterally the length of each side, typical of the Hemlock Sawfly, *N. tsugae* (Hard et al. 1976. Hemlock Sawfly. USDA Forest Service, Forest Insect and Disease Leaflet. Online at: http://www.fs.fed.us/r6/nr/fid/fidls/fidl31.pdf). The relatively intact larger of the two larvae (ca. 20 mm total length [TL]), was pale green, had a black head capsule with a lighter dorsal patch, and matched the size of the last larval (= pre-pupal) instar of *N. tsugae* (Hard et al. 1976, *op. cit.*). The smaller larva (15 mm TL), consisted of only a head and outer skin, but we could not distinguish whether this was from digestion or simply represented a previously shed larval skin consumed by the salamander.

At 1056 h on 11 July 2007, DEM made a second observation while sampling at the same site. A larval *R. kezeri* (30 mm SVL, 16 mm tail), found beneath a cobble in a riffle 282 m upstream from the first observation, had a *Neodiprion* larva (ca. 10 mm TL) sticking out of its mouth. As previously, the larva was immediately preserved. This larva was similar to the previous two, but the striping was less pronounced, and the head capsule was mostly white with black shading.

Sawflies are hymenopterans known for their phytophagous larvae (Smith 1993. *In* Wagner and Raffa [eds.], Sawfly Life History and Adaptations to Woody Plants, pp. 3–32. Academic Press, Inc., San Diego, California). Members of *Neodiprion* feed exclusively on conifers, tend toward monophagy (feed on but one host species), and several species are well known for eruptions in larval numbers that can defoliate large areas (Haack and Mattson 1993. *In* Wagner and Raffa [eds.], *op. cit.*, pp, 503–545). Given *Neodiprion* life history and that mature *N. tsugae* larvae are active from late June through August (Hard et al. 1976, *op. cit.*), opportunity exists for sawfly larvae to serve as an important seasonal food source for forest-dwelling species. Prepupal migration is not well understood, but if *N. tsugae* larvae fall from the canopy and initiate pupation, typically in August, either terrestrially or in low shrubs (Hard et al. 1976, *op. cit.*), those that drop into aquatic habitats may become prey for torrent salamanders.

Fieldwork was supported by the Forests and Fish Adaptive Management Program, Washington Department of Fish and Wildlife (WDFW). WDNR facilitated work on their land. Studies were done under a programmatic WDFW handling permit provided to employees in the course of their work. David R. Smith, research entomologist (retired, Systematic Entomology Labo-

ratory, Agricultural Research Service, U.S. Dept. Agriculture, Beltsville, Maryland) identified both larvae collected on 09 July 2007 as *Neodiprion*. R. Bruce Bury provided helpful comments. This is contribution No. 20 of the WDFW Habitat Program Amphibian Research Group.

ANURA — FROGS

ALSODES PEHUENCHE (NCN). **LARVAL BIOLOGY.** *Alsodes pehuenche* is a telmatobiine frog known only from the type locality, the Pehuenche Valley in the Central Andes of Argentina, on the border with Chile (Cei 1976. Atti. Soc. Ital. Sci. Nat. Museo Civ. Stor. Nat. Milano 117[3–4]:159–164). Its tadpole was described as belonging to *Telmatobius montanus* (Cei and Roig 1965. Copeia 1965[4]:421–425), but was later re-assigned to *Alsodes pehuenche* (Cei 1976, *op. cit.*). The species was described from mountain snowmelt streams with stony banks covered in herbaceous vegetation, near permanent snow, and from ponds of spring water, probably thermal, rich in sulphurous deposits (Cei 1965. Publ. Occ. Inst. Biol. Univ. Nac. Cuyo 7:1–4; Cei and Roig 1965, *op. cit.*; Cei 1976, *op. cit.*). Since the species was first described (Cei 1976, *op. cit.*), no contributions have been made to the knowledge of its biology, and its current population status is unknown. The species has been categorized as Data Deficient (IUCN et al. 2004. Global Amphibian Assessment. <www.globalamphibians.org>). This note provides life history information on the larval population structure and larval habitat of the species.

During February 2007 (austral summer) two visits were made to the type locality in the Pehuenche Valley (WGS 84, 35.97342°S, 7038181°W, 2523 m elev.), in western Mendoza Province, Malargüe Department, Argentina. Habitat is a high mountain, steep, desert landscape, with wet meadows and snowmelt streams. The climate is harsh and is characterized by a long winter and a short favorable season. Average precipitation (mainly in the form of snow) is 800 mm annually. The area is inaccessible from May to November (Cei and Videla 2003. Bol. Mus. Reg. Sci. Nat. Torino 20[2]:275–290). Following Cei's 1964 itinerary, we travelled ca. 30 km along Provincial Route Nº 224 towards Paso Pehuenche along the Pehuenche Valley (1900–2530 m elev) in search of *Alsodes pehuenche* tadpoles in streams, meadows, and temporary pools. Of nine streams visited, *A. pehuenche* tadpoles were found only in the four located nearest to the International Pass, between 2491 and 2523 m elev, in agreement with Cei (1965, *op. cit.*). The frog *Pleurodema bufoninum* was found in temporary pools, and no anurans were found in the meadows.

Streams with *A. pehuenche* tadpoles are in very steep areas, although they have long stretches with gentle gradients and numerous waterfalls, and are surrounded by wet meadows. They have a maximum width of 2 m, carry a low volume of water and are exposed to strong summer radiation, with water temperature reaching 19°C at midday. Streambeds are stony, with fine organic sediment; periphyton and bacteria form a conspicuous reddish brown layer on the bottom. Snowmelt water in the streams is pure and contains a low concentration of ions, having very low conductivity (28–41μS/cm) and low hardness ($CaCO_3$ 11.68–15.01 mg/l). The concentration of sulphur is also very low (sulphides 0.3–2.44 mg/l). The pH was 5.9–7. No sulphur springs were found in the area. Midday air temperature was ca. 22°C. The tadpoles observed were concentrated in backwater sections of the streams. Groups were found ranging from 12–15 tadpoles occupying a surface area of 0.3 × 0.5 m or 0.5 × 0.8m, to groups of 50 tadpoles occupying surface areas of 1 × 1 m, giving density estimates ranging from 30 to 80 individuals/m^2. In all the streams, we found different cohorts of tadpoles of different sizes and stages (Gosner 1960. Herpetologica 16:183–190) living together, including newly hatched tadpoles (< 20 mm, Stage 25), medium-sized tadpoles (40 mm, Stage 26), large tadpoles (54–58 mm, Stages 31–34), and tadpoles near metamorphosis (62 mm, Stage 41; 57 mm, Stage 42).

Alsodes pehuenche tadpoles seem to prefer backwater sections of the streams, as they have no morphological adaptations to fast-flowing waters. None of the streams where *A. pehuenche* was found had characteristics of thermal waters with sulphurous deposits, nor any sign of volcanic activity. Cei and Roig (1965, *op. cit.*) mentioned finding adults and tadpoles in a "natural sulphur spring." There are two possible explanations for this statement. They may have mistaken the reddish-brown sediments (characteristic of these streams that drain wet meadows), for sulphurous deposits, perhaps influenced by the fact that the Termas de Cajón Grande hot springs, with their sulphurous pools, are located 20–30 km E of the area. The other possible explanation is that in 1964 there may have been an upwelling of sulphurous water that later disappeared as a result of the dynamics of volcanism itself.

Of the 17 species of the genus *Alsodes*, only *A. pehuenche*, *A. gargola*, *A. tumultuosus*, and *A. montanus* inhabit high mountain bodies of water in the Andes Range with similar environmental restrictions. The type locality of *A. pehuenche* has snowmelt streams with low conductivity and hardness, a long winter period with snow cover seven months a year, and an abrupt transition to summer with strong radiation and high temperatures, as do the high elevation localities of *Alsodes gargola* (Logares and Úbeda 2004. Herpetol. Rev. 35:368–369; Logares and Úbeda 2006. Amphibia-Reptilia 27[2]:263–267), *A. tumultuosus*, and *A. montanus* (Díaz and Valencia 1985. Oecologia 66:353–357). In this type of environmental scenario, the *A. pehuenche* tadpole development pattern bears similarities with the other three species.

The cohort of small, Gosner Stage 25 tadpoles found in February indicate a recent hatch during the summer that samples were taken. Similarly, for *A. montanus* and *A. tumultuosus*, early tadpoles (Stages 25–26) were reported in December–January (Díaz and Valencia 1985, *op. cit.*), and it was suggested that spawning occurred early in the favorable season. Similarly, *A. gargola* tadpoles hatch during a limited period in mid-summer (January–February) (C. Úbeda, pers. obs.). Cei and Roig (1965, *op. cit.*) mentioned the coexistence of *A. pehuenche* tadpoles of all stages and assumed that this could be due to repeated ovipositions during the summer season. Nevertheless, the large differences in size and development stage found among cohorts show that they belong

to ovipositions of different summers, as reported for *A. gargola*, for which there are up to three simultaneous cohorts of tadpoles, each cohort having hatched during a different summer (Logares and Úbeda 2004, *op. cit*.).

Cei (1965, *op. cit*.) suggested that tadpoles probably do not complete metamorphosis in a single period, but their larval life extends over two annual cycles. Our field observations support a long larval period in *A. pehuenche* and tadpole overwintering for at least two winters. It has now been shown that *A. gargola* tadpoles overwinter in high Patagonian Andean aquatic environments subject to a long winter season with snow cover (Logares and Úbeda 2004, 2006, *op. cit*.). An extended larval stage, tadpoles that overwinter, and a similar pattern of sizes and stages have also been found for *A. montanus* and *A. tumultuosus* (Díaz and Valencia 1985, *op. cit*.).

Our finding of *A. pehuenche* tadpoles nearing transformation in the middle of the favorable season matches the date recorded for *A. gargola* (Logares and Úbeda 2004, *op. cit*.), *A. tumultuosus*, and *A. montanus*, which had large metamorphosing larvae at the beginning of the favorable season, and recently transformed froglets during summer (December–March) (Díaz and Valencia 1985, *op. cit*.).

The habitat of *A. pehuenche* may soon be altered when the road through the Andes between Argentina and Chile is paved. Traffic is expected to increase over the following years, along with the consequent impact on the only known populations of the species. The streams occupied by *A. pehuenche* cross the road, and tadpoles have been found just a few meters upstream and downstream from the road. Although this contribution provides new information on basic aspects of larval natural history and microhabitat, further studies are needed. Because of this species' restricted range and the lack of information on its biology, we believe that further studies are urgently needed to develop conservation plans.

We thank Dirección de Recursos Naturales Renovables de la Provincia de Mendoza for subsidizing water analysis, and Gustavo Baffico for helpful comments on the interpretation on these analyses.

ASCAPHUS TRUEI (Coastal Tailed Frog). **ATYPICAL AMPLEXUS.** Cross-species amplectic behavior has been reported with some frequency among anurans, but reports are limited to lentic-breeding amphibians (Brodie 1968. Herpetologica 24:86; Brown 1977. J. Herpetol. 11:92–94; Storm 1952. Herpetologica 8:108). Herein, we report the first observed case of inter-species amplexus involving the stream-breeding *Ascaphus truei*.

This observation was made on a small (< 1 m wide), 1st-order (Strahler 1952. Geol. Soc. Am. Bull. 63:1117–1142), seasonally intermittent, non-fish-bearing stream, a tributary of the South Fork Willapa River, Pacific County, Washington, USA (WGS 84, 46.585°N, 123.731°W, elev. 248 m). This site, located in a 50-year old second-growth forest managed for timber by the Washington Department of Natural Resources (WDNR), is dominated by Western Hemlock (*Tsuga heterophylla*) with Sword Fern (*Polystichum munitum*) and Oregon Oxalis (*Oxalis oregona*) in the understory.

On 15 May 2007, KMP and TRC found an adult (38 mm SVL) male *A. truei* in amplexus with a dead juvenile (45 mm SVL) *Rana aurora* in a small (0.8 m long, 11 cm deep) gravel-dominated pool. Both frogs were encountered ventral side up with the *A. truei* clasping the waist of the *R. aurora*. The *R. aurora*, dead, was slightly bloated, had its digestive track partly everted through its mouth, its left hand missing, and only one digit on its right hand. The male tailed frog's "tail" appendage was erect, directed anteriorly, and visibly engorged. Notably, the *A. truei* made no obvious response when picked up with the *R. aurora* from the pool, becoming active only after it was carefully removed for measurement from its firm grip on the dead *R. aurora*. The *A. truei* was released at the point of capture and the *R. aurora* was discarded.

Whether the *R. aurora* died before or after being clasped is unclear. The typical amplectic posture by the male *A. truei* (Slater 1931. Copeia 1931:62–63; Wemz 1969. J. Herpetol. 3:167–169) involves hand clasping from an inguinal position. This appeared to direct pressure on the mid-abdomen, and may have resulted in the partial eversion of the digestive track we observed. Moreover, if the *R. aurora* was alive when clasped, as a juvenile, it would not have responded. Noble and Aronson (1942. Bull. Am. Mus. Nat. Hist. 80:127–142) showed experimentally that frog girth represents a primary amplectic inducement for male frogs, so the *A. truei* may have perceived the juvenile *R. aurora* as a key stimulus; the juvenile *R. aurora* was about the size and shape of a gravid female *A. truei*.

Fieldwork was supported by the Forests and Fish Adaptive Management Program, Washington Department of Fish and Wildlife (WDFW). WDNR facilitated work on their land. Studies were done under a programmatic WDFW handling permit provided to employees in the course of their work. This is contribution No. 21 of the Forests and Fish Section of the WDFW Habitat Program Amphibian Research Group.

BOKERMANNOHYLA CIRCUMDATA (Espirito Santo Treefrog). **PREDATION.** Amphibians are commonly preyed upon by spiders and snakes (Neill 1948. Herpetologica 4:158; Rowe

et al. 2000. Herpetol. Nat. Hist. 7:145–152; Aucone and Card 2002. Herpetol. Rev. 33:48). The treefrog *Bokermannohyla circumdata* occurs in the Cerrado and Atlantic Forest of Brazil. This terrestrial, nocturnal treefrog is associated with forested areas and is usually found on tree trunks or branches close to water bodies (Eterovick and Sazima 2004. Amphibians from the Serra do Cipó. PUC Minas, Belo Horizonte; Izecksohn and Carvalho-e-Silva 2001. Anfíbios do Município do Rio de Janeiro. Editora Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil). *Xenodon neuwiedii* is a terrestrial and diurnal snake species that feeds strictly on anurans (Jordão 1996. Master´s thesis. Instituto de Biociências, Universidade de São Paulo, São Paulo. 93 pp.; Silva and Rodrigues 2001. Herpetol. Rev. 32:188). Herein, we report predation of an adult *B. circumdata* in Atlantic High Montane Forest in the Duas Barras Farm, Santa Maria do Salto (10.7693°N, 41.3501°W, SAD 69; 950 m elev.), Minas Gerais, southeastern Brazil. On 2 May 2005, between 1000 and 1040 h, one of us (AS) observed an adult *Xenodon neuwiedii* (ca. 450 mm TL) on a fallen tree near the permanent stream's edge (Fig. 1) preying on a adult *B. circumdata* (ca. 80 mm SVL). The snake used its jaws to support and ingest the treefrog headfirst, while maintaining its tail curled in a thin branch.

FIG. 1. *Bokermannohyla circumdata* preyed upon by *Xenodon neuwiedii*, Minas Gerais, southeastern Brazil, May 2005.

DENDROPSOPHUS LEUCOPHYLLATUS (Bereis' Tree Frog). **PREDATION.** Spiders are known to prey on frogs, including species of *Dendropsophus* (Pramuk and Alamillo 2002. Herpetol. Rev. 33:46). Herein, we provide the first record of a spider of the genus *Ancylometes* (Araneae: Ctenidae) feeding on *D. leucophyllatus*. On 8 Jan 2006 at 2310 h AS observed an adult *D. leucophyllatus* being eaten by an adult spider near a small temporary pond located on the Hacienda San Sebastian, Provincia Ñuflo de Chavez, Dept. Santa Cruz, Bolivia (WGS 84, 16.383°S, 62.010°W, 566 m elev.) (Fig. 1). At the time of observation, the spider was observed motionless in the grass 25 cm from the pond's border. When the frog jumped nearby, the spider caught it and immediately began feeding.

Spider identification was verified by H. Hoefer (Staatliches Museum für Naturkunde, Karlsruhe, Germany) by photographs.

ELEUTHERODACTYLUS COQUI (Coquí). **PREDATION**. This endemic frog from Puerto Rico is distributed along the island, concentrated mainly in two distinct large populations (Velo-Antón et al. 2007. Mol. Phylogenet. Evol. 45:716–728). Many natural predators are known for this frog, including scorpions, spiders, frogs, lizards, birds, and mammals (Joglar 2005. *In* Joglar [ed.], Biodiversidad de Puerto Rico, Vertebrados Terrestres y Ecosistemas, Serie de Historia Natural, pp. 37–96. Editorial del Instituto de Cultura Puertorriqueña). Sympatric tarantulas and spiders (Sprassidae, genera *Olios* and *Stasina*) have been documented as important predators (Formanowicz et al. 1981. Herpetologica 37[3]:125–129; Stewart 1985. J. Herpetol. 19[3]:391–401). Ctenidae and Ctenizidae spiders have also been reported as predators (Formanowicz et al., *op. cit.*; Stewart and Woolbright 1996. *In* Reagan and Waide [eds.], The Food Web of a Tropical

Rain Forest, pp. 302–309. University of Chicago Press, Chicago, Illinois).

On 5 July 2006 we observed a ground spider (Corinnidae) attacking a juvenile *E. coqui* (Fig. 1). This event took place at 2227 h (27°C) in Las Casas de la Selva, Patillas, a rainforest reserve in the southern central highlands of Patillas, Puerto Rico (WGS 84, 18.067°N, 66.033°W). The attack took place on the forest floor over leaf litter. A sequence of 12 photographs taken in ca. 1 minute intervals revealed that the spider struck the frog by sticking its chelicerae in the dorsal pelvic girdle region, presumably injecting venom to the sciatic nerves of the frog. Once the frog was subdued, the spider released it, and walked away. The frog remained immobile with both legs paralyzed, and died about 1 min later; unfortunately, the spider escaped without capture. Because the SVL of the frog was comparable to the spider's cephalothorax + abdomen length, we think it is unlikely that the spider could have engulfed its prey whole. Instead, we suggest that this spider's foraging strategy is to stun its prey with venom, and later return to suck the juices of a partially digested protein-rich meal.

We are grateful to the Tropic Ventures staff at Las Casas de la Selva for allowing us to work in their property, to G. Muriente-Pastrana for the photographs, to N. I. Platnick, D. R. Smith, J. Mercado, and A. Bonaldo for speculating on the identity of the spider, and to R. L Joglar for comments on earlier versions of this note.

ELEUTHERODACTYLUS RICHMONDI (Coquí Caoba). **REPRODUCTION.** *Eleutherodactylus richmondi* is a medium-sized frog (female max SVL 43.5 mm), found in the interior uplands of Puerto Rico; females are usually found on the forest floor and males call from the lower vegetation up to 1.5 m above ground (Joglar 1998. Los Coquíes de Puerto Rico: Su Historia Natural y Conservación, Editorial de la Universidad de Puerto Rico, San Juan. 232 pp.). Herein, we offer the first report of reproduction in *E. richmondi* since 1962 and include information on nesting site, parental care, clutch and egg size, and SVL of newly hatched juveniles.

Two egg clutches were found on 31 Jan 07 in the Carite Forest Reserve in eastern Puerto Rico. Both clutches were found inside a fallen tree-fern log on the forest floor and were separated from each other by a distance of 25 cm. An adult female *E. richmondi* was found inside the log, suggesting some degree of parental care. There are previous reports suggesting parental care for this species but it was unknown which parent provides such care (Joglar 1998, *op. cit.*). One of the clutches (UPRRP 6394) was in an advanced stage of development and contained 29 eggs (mean = 5.76 mm diameter; range = 5.4–6.3; N = 5). Fully formed embryos were readily observed and exhibited the typical brown and brick color pattern of the adult. This characteristic facilitates clutch identification at advanced stages. Eggs began hatching on 1 Feb 07 and in less than 24 h, 20 of 29 eggs hatched. Mean SVL of newly hatched juveniles was 7.7 mm (7.5–8.0; N = 20). By 4 Feb, only 21 of 29 eggs hatched. The second clutch (UPRRP 6393) was comprised of more recently deposited eggs and contained 29 eggs (mean = 5.26 mm diameter; 5.0–5.5; N = 5).

We thank V. Vélez, S. Ocasio, R. Cordero, J. Fuentes, G. Vázquez, and J. D. Daza for fieldwork and P. A. Burrowes for reviewing this note.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-mouthed Toad). **HIND LIMB MALFORMATION**. Amphibian malformations are one of the major concerns in the loss of global amphibian biodiversity. Some abnormalities are a result of mutation, developmental errors, or trauma; however, these occurrences are thought to be uncommon and most often result in missing digits or parts of a limb (Blaustein and Johnson 2003. Front. Ecol. En-

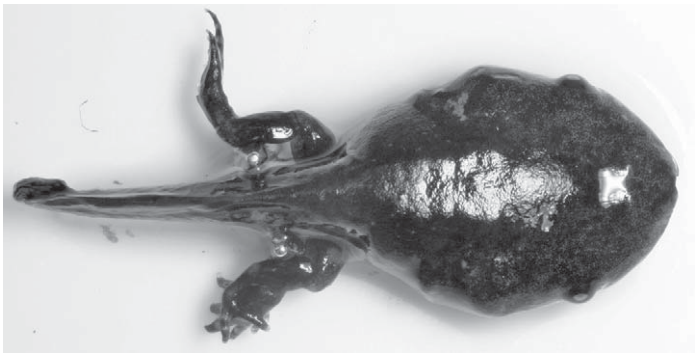

FIG. 1. Dorsal surface of *Gastrophryne carolinensis* tadpole with malformed right hind limb.

viron. 1:87–94). Other causes of amphibian malformations are UV radiation, chemical contamination, and parasitic infection (Blaustein and Johnson 2003, *op. cit.*). These types of exposures can result in a wide range of malformations from whole body abnormalities to missing limbs and/or digits to extra limbs and/or digits. Although it is known that UV radiation, chemical contamination, and parasitic infection can cause malformations, it is likely these variables interact with each other. Because the complex interaction of all three is unclear, we can better understand the mechanisms that cause deformities by adding to the growing breadth of knowledge on amphibian malformations.

We collected 200 larval *Gastrophryne carolinensis* from a permanent manmade wildlife pond in the Davy Crockett National Forest, Houston County, Texas, USA on 8 Aug 2007. The pond was created in 1992 and is located in a 72-acre Short-leaf Pine (*Pinus echinata*) stand. The stand was planted in 1990 and received a prescribed burn in 2003 and 2005 and has not been treated with herbicides or pesticides. Upon observation we noticed that one of the larvae had a malformed right hind limb. The lower portion of the right hind limb is enlarged (Fig. 1); however, it is unclear if the tibiafibula is duplicated. Also, the right hind foot has 13 digits that are oriented ventrally (Fig. 2A, 2B). The left hind limb is normal and the left hind foot has 5 normally positioned digits (Fig. 2A, 2C). The larva is Gosner Stage 41 (Gosner 1960. Herpetologica 16:183–190) and has a broken tail. After close examination we concluded that the type of malformation could be polymelia, polydactyly, or polyphalangy (Meteyer 2000. Biological Science Report USGS/BRD/BSR-200-0005), or some combination of the three. Of the 200 individuals that were collected at this site this was the only one that had malformations. To our knowledge this is the first record of hind limb malformations in *G. carolinensis*. The larva was deposited in the Texas Cooperative Wildlife Collections, TCWC 92886.

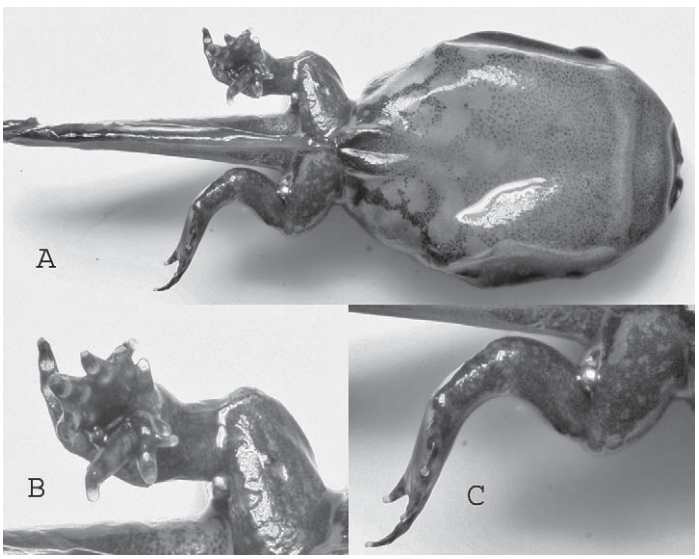

FIG 2. (A) Ventral surface of *Gastrophryne carolinensis* tadpole with malformed right hind limb. (B) Right hind limb of *Gastrophryne carolinensis* with 13 digits. (C) Normal right hind limb of same individual.

LEPTODACTYLUS DIPTYX (Tropical Bullfrog). **ENDOPARASITES**. *Leptodactylus diptyx* occurs in the Lower Chaco and oriental region of Paraguay; eastern lowlands of Santa Cruz (Bolivia), and northern Argentina (IUCN 2007. Conservation International and NatureServe. Global Amphibians Assessment. http://www.globalamphibians.org. Accessed 22 Oct 2007). To our knowledge, no previous report of parasitism exists for *L. diptyx*. The purpose of this note is to report *Catadiscus* sp. (Trematoda) and *Centrorhynchus* sp. (Acanthocephala) in *Leptodactylus diptyx* from Argentina. Two adult *Catadiscus* sp. in large intestine and five acanthocephalan larvae *Centrorhynchus* sp. in the coelomic cavity were found in a female *L. diptyx* (27.6 mm SVL) from the herpetological collection of Universidad Nacional del Nordeste (UNNEC 9000) collected 22 Nov 2006, Corrientes (city), Corrientes Province (WGS 84, 27.466°S, 58.783°W, elev. 65 m). In Argentina, species of *Catadiscus* are known from the anurans *Leptodactylus latinasus*, *Leptodactylus ocellatus*, *Pseudopaludicola boliviana*, *Lysapsus limellus*, *Pseudis minuta*, *Pseudis paradoxa*, and *Hypsiboas pulchellus* (Lunaschi and Drago 2007. Zootaxa 1476:51–68). *Centrorhynchus* sp. has been documented from several South American amphibians (Smales 2007. Zootaxa 1445:49–56; Smales 2007. J. Parasitol. 93[2]:392–398), but only two species from Argentina: *Leptodactylus latinasus* and *Leptodactylus bufonius* from Corrientes Province (Hamann et al. 2006. Acta Parasitol. 51[4]:294–299; González and Hamann 2006. Rev. Esp. Herpetol. 20:39–46).

Leptodactylus diptyx represents a new host record for *Catadiscus* sp. and *Centrorhynchus* sp. We thank L. Lunaschi for verification of the organisms.

LITORIA RANIFORMIS (Southern Bell Frog). **CLUTCH SIZE.** Currently, there is no documented assessment of the clutch

size of *Litoria raniformis*. A recent review of the biology of *L. raniformis* suggested that the number could range from several hundred, as indicated by dissections, up to thousands as in the closely related *L. aurea* (Pyke 2002. Austral. Zool. 32:32–48). Five amplecting pairs of *L. raniformis* were caught in Central Otago, South Island, New Zealand on the night of 30 Oct 2007. These pairs were housed in separate containers until they laid eggs, after which the frogs were removed and the eggs counted. The five clutches contained the following numbers of eggs: 2448, 3090, 3191, 3644, and 4563. *Litoria aurea* is known to lay an average of 5000 eggs with large clutches reaching over 11,000 eggs (van de Mortel and Goldingay 1996. Austral. Zool. 30:398–404). This suggests that the clutch sizes of *L. raniformis* are smaller than that of similarly-sized *L. aurea*.

OOPHAGA PUMILIO (Strawberry Poison Frog). **PARENTAL CARE.** Parental care is complex in dendrobatid frogs, all of which are diurnal and transport tadpoles (Duellman and Trueb 1994. Biology of Amphibians. Johns Hopkins Univ. Press. Baltimore, Maryland. 670 pp.). On 5 July 2007 at 1047 h at Popa Island, in the Bocas Del Toro Archipelago, Panama, I observed a male *Oophaga pumilio* carrying a wriggling tadpole on his back (Fig. 1). The frog was observed on the southern part of the island, in an open area adjacent to the coast. The male was discovered while it was calling among numerous calling males at the same site. The male moved when the chorus stopped, but when the chorus began again the male stopped moving and started to call. The behavior continued for ca. 20 minutes, after which the male climbed up the tree until lost from sight. This is the first report of a male *O. pumilio* transporting tadpoles in the field since the first report from captive individuals (Weygoldt 1980. Behav. Ecol. Sociobiol. 7:329–332).

FIG. 1. *Oophaga pumilio* male carrying a tadpole up a *Ficus* sp., 5 July 2007, at Popa Island, Bocas Del Toro Province, Panama.

RANA BOYLII (Foothill Yellow-legged Frog). **NECROGAMY.** Necrogamy has not been reported in *Rana boylii*. Here we report on a male *R. boylii* attempting to amplex with a dead female *R. boylii*. During *R. boylii* egg mass surveys on Canyon Creek, Trinity County, California, USA conducted on 20 June 2006, an adult male *R. boylii* was photographed in amplexus with a long-deceased female *R. boylii* at 1328 h. (Fig. 1.). The deceased female was badly decomposed and covered with a film of fungal hyphae. Measurements of animals were not taken to avoid disturbing the mating event. This behavior may have negative implications with disease transmission of pathogens such as *Batrachochytrium dendrobatidis* or iridoviruses.

FIG. 1. Male *Rana boylii* in amplexus with deceased female conspecific in Canyon Creek, Trinity County, California.

RANA CATESBEIANA (American Bullfrog). **PREDATION.** Although predation on amphibians by Western Burrowing Owls (*Athene cunicularia hypugaea*) has been previously documented (Bond 1942. Condor 44:183; Clark 2008. Herpetol. Rev. 39:80–81; Green et al. 1993. Northwest Sci. 67[2]:88–93; Hoetker and

Gobalet 1999. J. Raptor Res. 33[4]:333–335; Munro 1929. Condor 31[3]:112–116; Scott 1940. Amer. Midl. Nat. 24[3]:585–593; Thomsen 1971. Condor 73:177–192), published documentation of predation on *Rana catesbeiana* is lacking. We observed numerous dead *R. catesbeiana* at the entrance of a Western Burrowing Owl burrow adjacent to a cattle stock pond within a vernal pool complex near Roseville, Placer County, California, USA (NAD 83, 38.8222°N, 121.3847°W) on 23 Sept 2003. Forty-three late-stage tadpoles and subadult *R. catesbeiana*, ranging from ca. 30–80 mm SVL, were collected at the burrow entrance. All of the frogs were desiccated and were missing brain cases or their entire head. Although this is the first published report of Western Burrowing Owl predation on *R. catesbeiana* of which we are aware, similar instances of predation, including brain case consumption, have been observed on other amphibians including California Tiger Salamander (*Ambystoma californiense*), Couch's Spadefoot (*Scaphiopus couchii*), and Great Plains Toad (*Bufo cognatus*) (C. Conway, pers. obs.; L. Rugge, pers. comm.).

TELMATOBIUS OXYCEPHALUS (NCN). **PREDATION.** Herein I report two cases of predation on juvenile and adult *Telmatobius oxycephalus*. The observations were made during 15–17 Aug, 18–21 Dec, 27–30 Dec, 2006 and 29 Jan–1 Feb 2007 at two branches of a small stream tributary of the Huasamayo River 10 km from the city of Tilcara, province of Jujuy, northern Argentina.

On 31 Jan 2007 at 2110 h, a non-adult wolf spider (*Lycosa cf. thorrelli*; Lycosidae) was observed hidden under a small rock at the margin of a branch of the stream (max width 1 m) preying upon a juvenile *T. oxycephalus*. Only the hindlegs of the frog were distinguishable because the spider covered the rest of the specimen with its body. When found the frog was dead and a large area of necrotic tissue existed in the dorsal area; the whole body was a pallid color. The spider remained motionless for ca. 10 min. and then left the prey when it was disturbed during an attempt to collect it.

On 12 Dec 2006 at 2000 h, a Rainbow Trout (*Oncorhynchus mykiss*) was collected from a pool ca. 30 cm from the stream. The pool was ca. 150 × 80 cm, 50 cm deep, and had clear water; water temp. was 9°C, and air temp. was 17°C. As the pond did not have direct connection with the stream it is possible that the trout got there during a flood that occurred a week prior to the observations. Searching under the stones around the pool yielded a live female *T. oxycephalus* (SVL = 44.8 cm). Upon dissection of the trout, an adult *T. oxycephalus* (SVL = 45 cm) in an intermediate state of digestion was found in the stomach. The inhabitants of the area reported that Rainbow Trout have been released in the area annually for at least three years. However, they indicated that the summer floods cause high mortality and drive the adult trout downstream where they likely die because of water turbidity. Additional searches were conducted at the site but no other trout were found. These observations indicate that introduced salmonids do prey on *Telmatobius*. Although suspected (Merino-Viteri et al. 2005. Monog. Herpetol. 7:9–37), I am unaware of any published report of predation, although trout are known to prey on other anurans (e.g., Bradford et al. 1993. Cons. Biol. 7[4]:882–888; Fox et al. 2005 Copeia 2005:921–929; Katz et al. 2003. Div. Distrib. 9:99–110; Lips et al. 2005. Biotropica 37[2]:222–226). Whether this predation occurs at a scale that could drive local populations to extirpation, as suggested for *Telmatobius ceiorum* (Barrionuevo and Ponssa 2008. Herpetologica 64:47–62), remains to be studied.

The specimens of *T. oxycephalus*, the stomach of *O. mykiss*, and the spider are deposited at the Museo Argentino de Ciencias Naturales "Bernardino Rivadavia" División Herpetología.

I thank Julian Faivovich for provide helpful comments on this manuscript and L. Piacentini for identification of the spider.

TURTLES

ACTINEMYS MARMORATA (Western Pond Turtle). **PREDATION ATTEMPT.** *Actinemys marmorata* inhabits a variety of aquatic habitats from western Washington, USA south to northwestern Baja California, Mexico (Stebbins 2003. Western Reptiles and Amphibians. Third Ed. Houghton Mifflin. New York, New York. 533 pp.) and is a California Species of Special Concern (Jennings and Hayes 1994. Amphibian and Reptile Species of Special Concern in California. Report to the California Department of Fish and Game, Rancho Cordova, California. 260 pp.). Among the predators that are known to feed on *A. marmorata* is the North American River Otter (*Lontra canadensis*). Manning (1990. Northwest. Nat. 71:38–42) observed cracked and chewed *A. marmorata* shells as well as a live individual with all four legs bitten off, which was attributed to predation by *L. canadensis*. However, no direct observations of *L. canadensis* feeding on *A. marmorata* have been documented.

On the morning of 31 May 2006 I observed eight *A. marmorata* basking on a large boulder along the edge of the Klamath River near Yreka, California (41.861315°N, 122.566127°W) from the opposite bank using binoculars. As I watched these turtles at ca. 0845 h, three *L. canadensis* leaped from the water, in unison, onto the rock. One *L. canadensis* came onto the rock from the downriver side, one from the upriver, and one from the middle. Each *L. canadensis* grasped an individual basking *A. marmorata* with their forelimbs and rolled back into the water. A fourth *L. canadensis* leapt onto the rock and made attempts to capture another escaping *A. marmorata*, but was unsuccessful. As the attack ensued, the remaining five *A. marmorata* quickly fled into the river. Shortly after, the three successful predator otters returned to the rock, and all four otters scrambled around the boulder appearing to search for *A. marmorata*. All four otters then returned to the river channel and disappeared. After the attack, a boulder

on the same bank ca. 45 m upstream had two other basking *A. marmorata* that were undisturbed.

Many populations of *A. marmorata* are sensitive to factors that affect reproduction and recruitment such as habitat loss, non-native predators, disturbance, water quality, and natural predation. Though actual predation on *A. marmorata* by *L. canadensis* was not confirmed during this observation, the cooperative hunting strategy utilized by *L. canadensis* during this observation provides insight into predator/prey interactions between these species.

PSEUDEMYS CONCINNA (Eastern River Cooter). **MOVEMENT**. On 24 July 2007 a female *Pseudemys concinna* (carapace length = 329 mm; mass = 4020 g), was uniquely marked by drilling holes in the marginal scutes (ID = 655) and released from a baited hoop trap at 1000 h. Later that same day (1500 h), it was recaptured 1470 m downstream during snorkeling surveys. Capture locations were determined with a Trimble Geo3 Explorer GPS (accuracy 1–5 m). To our knowledge, this is the longest daily movement recorded for *P. concinna*. On 6 July 2008 another female *P. concinna* (carapace length = 383 mm; mass = 5610g), was also uniquely marked (ID = 946) and released from a baited hoop trap at 0900 h. On 9 July 2008 at 1315 h, the same female was recaptured during a snorkel survey 6280 m downstream. A female and male *P. concinna* were observed to move a maximum distance of 358 and 321 m in a Virginia population over the course of a two-month study (Buhlmann and Vaughan 1991. J. Herpetol. 25:72–78). Dreslik et al. (2003. Chelon. Cons. Biol. 4:706–710) found *P. concinna* in an Illinois pond to move 336.9 m ± 200.9 m, with females moving 321.9 m ±197.3 m during the day. Marchand (1942. M.S. thesis, Univ. Florida, Gainesville. 113 pp.), during a two-year study, found that 14 *P. c. suwanniensis* moved, on average, > 640 m between recaptures and observed one movement of 8.9 km. It was mentioned that these movements may be attributed to extended handling and releasing groups of turtles at the same place. Long, linear movements of riverine turtle species have been attributed to nesting voyages by females (Moll and Moll 2005. The Ecology, Exploitation, and Conservation of River Turtles. Oxford University Press. New York). In the southern United States, *P. concinna* generally nest in May and June (Ernst et al. 2004. Turtles of the United States and Canada. Smithsonian Institution Press. Washington, D.C. 578 pp.). The two movements we observed may have been associated with either nesting or disturbance from handling, although attempts were made to minimize handling disturbance in the field.

Submitted by **SEAN C. STERRETT, LORA L. SMITH, M. BRENT HOWZE, AUBREY M. HEUPEL,** and **CARLA L. ATKINSON,** Joseph W. Jones Ecological Research Center, Route 2, Box 2324, Newton, Georgia 39870, USA (e-mail: sterretts@warnell.uga.edu).

TERRAPENE ORNATA (Ornate Box Turtle). **PREDATION ON CLIFF SWALLOWS**. Turtles are known to have broad, omnivorous diets that include plant material, aquatic and terrestrial invertebrates, and vertebrates (Klimstra and Newsome 1960. Ecology 41:639–647). During a 25-year study of Cliff Swallows (*Petrochelidon pyrrhonota*) in southwestern Nebraska, we observed *Terrapene ornata* prey, or attempt to prey, on swallows. Cliff Swallows feed exclusively on insects caught in flight. They are quick, agile fliers and rarely alight on the ground (Brown and Brown 1996. Coloniality in the Cliff Swallow: The Effect of Group Size on Social Behavior. University of Chicago Press. Chicago, Illinois). Consequently, they are very unlikely prey for turtles.

On 4 July 2002, one of us (MBB) was netting Cliff Swallows with a stationary mist-net placed near the entrance of a culvert underneath a railroad embankment near Keystone, Keith County, Nebraska, USA (41.3841667°N, 101.7988889°W). The colony consisted of 200 swallow nests. On one occasion as large numbers of birds flushed and hit the net, the weight of the birds pulled the net down to ground level. One *T. ornata*, which was seen regularly at the colony, approached one adult Cliff Swallow that was very low in the net and killed it by biting and eating its head. After killing the bird, the turtle walked away carrying the head. Nesting at Cliff Swallow colonies is usually quite synchronous (Brown and Brown 1996, *op. cit*.). Most colonies are initiated in mid-May, incubation lasts until mid-June, and most nestlings have fledged by mid-July. It is not uncommon for nestling Cliff Swallows to fall out of their nests (or jump out in response to nest parasites). Because these birds are too young to fly back to their nest and parent swallows do not attend nestlings on the ground, these nestlings become chilled, starve, and die. During peak periods of nesting synchrony, relatively large numbers of doomed nestlings can be found on the ground underneath nests at large colonies. From 2002–2007, at one large (1000–1800 nests) Cliff Swallow colony near Keystone, Keith County, Nebraska, USA (41.3555556°N, 101.6286111°W), we regularly observed two *T. ornata* patrolling the ground underneath the nests, killing and eating the moribund nestlings and scavenging dead nestlings. The turtles would walk up to nestlings that were alive and bite their heads, usually grabbing the nestlings by the front part of the head (in the beak and mouth area). Based on unique markings on their carapaces, we are confident that the same two turtles were present at this colony throughout the nesting season, and we suspect that the same two turtles returned to this colony site to feed for several consecutive years. *T. ornata* are known to be most active during June, which coincides with the swallow's nestling period (D. Ferraro, pers. comm.). *T. ornata* are rarely seen at colonies during the birds' incubation period or after most of the nestlings have fledged. Our observations are anecdotal in nature, but it appears that *T. ornata* recruit to and remain at Cliff Swallow colonies during the nestling period, when a reliable food resource is available.

Submitted by **MARY BOMBERGER BROWN**, Tern and Plover Conservation Partnership, University of Nebraska, Lincoln, Nebraska 68583-0931, USA (e-mail: mbrown9@unl.edu); and **CHARLES R. BROWN**, Department of Biological Sciences, University of Tulsa, Tulsa, Oklahoma 74104, USA.

SQUAMATA — SNAKES

AGKISTRODON CONTORTRIX MOKESON (Northern Copperhead). **MID-WINTER THERMOREGULATION.** On 6 January 2007, I found two adult *Agkistrodon contortrix mokeson* thermoregulating at their hibernacula (41.35°N, 74.27°W, 244 m elev.) Chester, New York, USA. The latest date this species has been observed above ground in New York is 4 November and the earliest reported emergence is 2 March. *Agkistrodon c. mokeson* was considered to be inactive during the brumation period in the winter (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America, 3rd edition. Houghton Mifflin, Boston. 450 pp.). Unusual warm weather probably contributed to this facultative basking. The average high temperature for 6 January is 1.7°C and the average low –7.8°C compared with the recorded high temperature of 21.1°C and the actual low temperature of 11.1°C on the day of this observation. This observation suggests that *A. c. mokeson* facultatively thermoregulates during winter months and appear to be able to detect external temperatures while in hibernacula.

Submitted by **BRYANT ABBUHL**, 28 Pine Hollow Road, Slingerlands, New York 12159, USA; e-mail: brymannol@aol.com.

AGKISTRODON PISCIVORUS LEUCOSTOMA (Western Cottonmouth). **SCAVENGING**. Scavenging by wild snakes is thought to be rare, and has been documented in only 26 species (reviewed in DeVault and Krochmal 2002. Herpetologica 58:429–436). Scavenging may actually be quite common, but rarely documented, because typical diet analysis makes it difficult to determine whether prey items were dead or alive when encountered. On 31 May 2004 at 2125 h, I observed a juvenile *A. piscivorus leucostoma* (~ 350 mm SVL) scavenge an adult, road-killed *Hyla cinerea* (~ 50 mm SVL) from County Road 1985, 3.4 rd mi W of Texas State Highway 124, in Chambers County, Texas, USA. The posterior end of the frog was stuck to the road, so that the snake had to pull several times in order to peel the frog off the road. After removing the frog from the road, the snake traveled into the grassy shoulder as it swallowed the frog. The road passes through marshy coastal plain, where there is a high density of amphibians, especially *Hyla cinerea* and *Rana sphenocephala*, and a variety of amphibian-eating snakes including five species of *Nerodia* and two species of *Thamnophis*, in addition to *A. piscivorus*. Road-killed amphibians are common after rains in this area, thus providing ample opportunity for scavenging of amphibians by snakes. This is only the second documented case of amphibian scavenging by a viperid in the wild (see DeVault and Krochmal, *op. cit*.). It is interesting that the species observed here was *A. piscivorus*, as Savitzky (1992. *In* Campbell and Brodie, Jr. [eds.], Biology of the Pitvipers, pp. 347–368. Selva, Tyler, Texas) suggests that the Cottonmouth is primarily a scavenger.

Submitted by **DAVID W. HALL**, Department of Biological Sciences and Texas Memorial Museum, The University of Texas, 1 University Station C0930, Austin, Texas 78712, USA.

ALSOPHIS PORTORICENSIS ANEGADAE (Racer). **CANNIBALISM.** Feeding on conspecifics is an uncommon but broadly observed phenomenon in snakes (e.g., Loveridge 1944. Copeia 1944:254; Lourdais et al. 2005. Biol. J. Linn. Soc. 84:767–774). However, it has not been previously reported in *Alsophis portoricensis* (Henderson and Powell. *In press*. Natural History of West Indian Amphibians and Reptiles. University Press of Florida, Gainesville). Here we report on several such cases observed on Guana Island, British Virgin Islands, in 2006.

The most definitive evidence for cannibalism occurring in nature was obtained on 12 October 2006, when staff alerted us to the presence of a dead snake at the dump. We found an adult male (596 mm SVL, 229 tail length [TL], MCZ R-184654) with the posterior end of a smaller female (545 SVL, 177 TL, MCZ R-184655) emerging from its mouth. Because the two snakes may have tried to swallow a single prey item, we dissected the specimen but found no prey item. The larger snake had abundant fat deposits and appeared in good condition. A second case occurred in captivity on 7 October, when two snakes were placed in a single cloth bag. Two days later, only the larger animal (female, 440 SVL, 247 TL, MCZ R-184643) could be found. Upon dissection it was found to contain the other individual, a hatchling (241 SVL, 116 TL, also MCZ R-184643). Hotel staff brought a third instance to our attention. They had observed two snakes "fighting" and photographed the event. Unfortunately, they did not allow the interaction to continue, but the photograph is inconsistent with known snake combat behavior, which has never been observed in this species. Instead, the larger individual had grasped the smaller snake behind the head, presumably in an attempt to subdue it for ingestion. The smaller snake was bleeding profusely, according to the report.

We are surprised that a behavior not noted in the past, despite extensive work on the species (e.g., Barun et al. 2007. Copeia 2007:93–100), appeared to be common this year. The past year had been unusually wet on Guana Island, vegetation is abundant, and anoles, the principal prey of *A. portoricensis*, are common. Consequently, the prevalence of cannibalism is difficult to explain. However, if cannibalism occurs frequently, that could explain why smaller animals were relatively uncommon in the sample examined by Barun et al. (*op. cit*.).

We thank A. Bates, V. Jardine, J. Lazell, and K. LeVering for assistance in the field and J. Rosado for curatorial assistance. Conservation Agency and Texas Tech University provided support. This is manuscript T-9-1119 of the College of Agricultural Sciences and Natural Resource Management, Texas Tech University.

ATROPOIDES OLMEC (Tuxtlan Jumping Pitviper). **REPRODUCTION and PARASITES.** *Atropoides olmec* is a terrestrial viviparous pitviper distributed as disjunct populations in the Sierra de Los Tuxtlas (Veracruz), Cerro Baúl (Oaxaca), and Ocozocuautla (Chiapas) in México and in Baja Verapaz, Guatemala. It occurs in upper tropical rainforest and cloud forest from elevations of 530–1100 m and probably higher (Campbell and Lamar 2004. The Venomous Reptiles of Western Hemisphere. Comstock Publishing

Associates, Ithaca, New York; Castoe et al. 2003. Herpetologica 59:421–432; Pérez-Higareda et al. 1985. Bull. Maryland. Herpetol. Soc. 21:97–106).

On 28 July 2006 we collected two gravid *A. olmec* females (580 mm SVL, 645 mm total length(CNAR 12230); 582 mm SVL, 644 mm total length) on El Bastonal, Santa Marta volcano, Catemaco, Veracruz, México (18.333°N, 94.89°W, WGS 84). Both were under rocks in a secondary forest at 1100 m elevation. The snakes were captured in order to obtain venom samples and were individually housed in cages at Instituto de Biotecnología, Universidad Nacional Autónoma de México (UNAM).

One of the snakes (CNAR 12230) never fed in captivity and died on 8 August 2006. Upon dissection we found 18 partially developed embryos (CNAR 12231–12248), ranging from 93–105 mm SVL (mean SVL = 101.9, SD = 3.3). We also found 23 adult hookworm nematodes *Kalicephalus inermis* (CNHE 5617) parasitizing her intestine and stomach. Nineteen of these were females ranging in length from 9.73–12.55 mm and four were males ranging in length from 8.23–10.02 mm. The other snake was maintained in captivity and gave birth to 15 live offspring on 15 October 2006. Neonates ranged from 161–186 mm SVL (mean SVL = 168.6 mm, SD = 8.3). This snake and two snakes of the litter are still alive in captivity at the Miguel Alvárez del Toro Zoo, Chiapas, México.

The only other report of litter size in this species is of a gravid female found at Los Tuxtlas in late May that birthed 12 offspring in mid-June (Pérez-Higareda et al. 2007. Serpientes de la Región de Los Tuxtlas, Veracruz, México. Guía de Identificación Ilustrada. Universidad Nacional Autónoma de México, Mexico City). Based on these three litters, mean litter size is 15 and falls within the range reported for other, closely related, *Atropoides* species (Campbell and Lamar, *op. cit.*; Solórzano-López 1989. Rev. Biol. Trop. 37:133–137, Solórzano-López 1990. Copeia 1990[4]:1154–1157).

Kalicephalus spp. nematodes have been reported from a broad spectrum of reptile hosts worldwide, mostly from snake species but also from several lizard species (Baker 1987. Occas. Pap. Biol., Memorial University of Newfoundland, St. John, Newfoundland; Schad 1962. Can. J. Zool. 40:1035–1165). *Kalicephalus inermis* has been described as a parasite of other genera of pitvipers (*Agkistrodon, Bothrops, Crotalus*) in America, including México (Baker 1987, *op. cit.*; Grego et al. 2004. Vet. Rec. 154:559–562; Pfaffenberger et al. 1989. J. Wildl. Dis. 25:305–306; Schad 1962, *op. cit*.). The life cycle of *K. inermis* is unknown, but direct development is suspected, with free living larvae and parasitic adults. Snakes can be infected experimentally by oral inoculation of third-stage larvae which invade the stomach or intestinal wall and become encapsulated in the mucosa where development to the fourth stage takes place. How snakes become infected under natural conditions is unknown. Because this reptile group tests their environment with their tongues, it is suggested that larvae might attach to the latter. There is also the possibility that infective larvae could invade soft-bodied animals such as snails, slugs and amphibians cohabiting with the snakes. There is no evidence that skin penetration occurs in snakes so ingestion is the most probable mechanism for infection (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. 2nd ed. CABI, International Publishing, New York; Schad 1956. Can. J. Zool. 43:425–452).

It has been reported that juvenile *Atropoides mexicanus* and *Atropoides occiduus* feed on orthopterans and lizards. Adults of these species (as well as *Atropoides nummifer*) feed on small rodents (Campbell and Lamar, *op. cit.*). No data on the natural diet of *A. olmec* are available, but in captivity both juvenile and adults fed on rodents (newborn and adult mice) and frogs (Pérez-Higareda et al. 2007, *op. cit*.).

The ecology of *A. olmec* has been poorly studied, and its habitat is fragmented, isolated, and dangerously subject to increasing pressure from human use. A better understanding of the species' natural history is necessary to help in conservation of the remaining populations. Specimens were deposited in the Colección Nacional de Anfibios y Reptiles (CNAR) and the Colección Nacional de Helmintos (CNHE), Instituto de Biología, Universidad Nacional Autónoma de México.

BOA CONSTRICTOR (Boa Constrictor)**. DIET**. *Boa constrictor* is a widely-distributed generalist predator that is abundant throughout many neotropical systems and is known to consume a wide variety of reptiles, mammals, and birds (Greene 1983. *In* Janzen [ed.], Costa Rican Natural History, pp. 380–383. University of Chicago Press, Chicago, Illinois). Avian prey taken by *B. constrictor* includes a diversity of ground- and canopy-dwelling species (Boback et al. 2000. Herpetol. Rev. 31:244–245; Sironi et al. 2000. Amphibia-Reptilia 21:226–232), yet the actual number of documented prey species remains relatively small. Here we report predation on an additional species of passerine bird, *Hylocichla mustelina* (Wood Thrush), at La Selva Biological Station, Puerto Viejo de Sarapiquí, Herédia Province, Costa Rica (10.4313°N, 84.0036°W). On April 6, 2005 at 1320 h, DLR was radio-tracking adult Wood Thrushes that had been equipped with external transmitter backpacks, and found that one bird (60–65 g, 20 cm long including tail feathers) had been consumed by a female *B. constrictor* (1203 mm SVL, 772.3 g). At the time of capture, the snake was resting on a 70 cm high branch, and had rectrices protruding from its mouth. We believe this to be the site of actual predation, because additional feathers were visible on the ground directly below the snake and tracked *H. mustelina* typically foraged in similar understory habitat. The snake was returned to the lab for data collection. Six days later it defecated 7.5 g of feathers, one partially-digested tarsus, the maxilla and mandible, and the 2 g intact transmitter, and subsequently was released at point of capture.

BOTHROPS JARARACUSSU (Jararacussu). **OPHIOPHAGY**. Ophiophagy in the wild has been reported for many species of the genus *Bothrops* (Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publ., Eagle Mountain, Utah). On March 2007 at 1130 h, we watched a *B. jararacussu* (ca. 500 mm TL) prey upon an adult of *Liophis miliaris* (Common Water Snake; ca. 500 mm TL) at Alto Ribeira State Park (24.583°S, 48.583°W), Iporanga, São Paulo, Brazil. The prey was partially inside of a crevice on the banks of a small stream and was swallowed head first. Marques et al. (2004. Herpetol. Rev. 35:58) reported *B. jararacussu* preying on *Chironius bicarinatus*.

I thank Luiz FML Ciscato and Reginaldo J. Silva (IQUSP) for the field observations.

Submitted by **MARCELO RIBEIRO DUARTE**, Laboratório de Herpetologia, Instituto Butantan, Av. Vital Brazil, 1500, CEP 05503-900, São Paulo, SP, Brazil; e-mail: mrduarte@butantan.gov.br.

BOTHROPS MOOJENI (Brazilian Lancehead). **PREDATION.** *Bothrops moojeni* is a large pitviper from riparian areas in Central and Southeastern Brazil (Nogueira et al. 2003. J. Herpetol. 37:653–659). On 23 Nov 2006 at 0723 h we found a juvenile *B. moojeni* (315 SVL) being eaten by a Tarantula (*Acanthoscurria* sp., Theraphosidae) above a rock in a semideciduous forest (18.0922222ºS, 57.4755556°W, WGS84 datum, 117 m elev.) in the Reserva Natural Engenheiro Eliezer Batista, Serra do Amolar, Brazilian Pantanal, Mato Grosso do Sul. The spider was holding the snake with its chelicerae. When disturbed, the spider fled while carrying the snake and attempted to hide under rocks. We captured the pair and released the spider. The snake was fixed in formalin and deposited at the Coleção Zoológica de Referência do Campus de Corumbá, Universidade Federal de Mato Grosso do Sul (CEUCH 3761). Invertebrates are known to prey on small, secretive snakes and juveniles of larger species (Greene 1997. Snakes: The Evolution of Mystery in Nature. University of California Press, Berkeley. 351 pp.), however most predators on pitvipers are vertebrates (e.g., Valdujo and Nogueira 2000. Herpetol. Rev. 31:45; Martins et al. 2003. Herpetol. Rev. 34:148; Oliveira and Santori 1999. Stud. Neotr. Fauna Environ. 34:72–75; Rodrigues 2005. Herpetol. Rev. 36:68). To the best of our knowledge this is the first published record of predation on *B. moojeni*.

We thank MMX Mineração e Metálicos S. A., Instituto Homem Pantaneiro, and Leonardo Hasenclever for assistance.

CACOPHIS CHURCHILLI (Northern Crowned Snake). **REPRODUCTION.** *Cacophis churchilli* is the only snake endemic to the Wet Tropics of Australia. A small cryptozoic elapid, it occurs in a range of habitats from rainforest to well-vegetated urban gardens, from sea level to 1000 m (Covacevich and McDonald 1993. Mem. Queensland Mus. 34:189–1999; pers. obs.). Very little is known of the natural history of this species beyond its present distribution and diet. Currently there is no published information on reproduction.

On 15 December 2006, a female was collected in the township of Atherton on the Atherton Tablelands (North Queensland) from an urban garden (17.2618°S, 145.4865°E). At the time the snake was "rescued" from the depredations of a domestic cat (*Felis catus*). Judging by the size and shape of the snake (330 mm SVL; 38 mm tail length; 12.8 g) it was thought to be gravid, an observation that was confirmed later in the day when the snake deposited four oblong eggs into a cloth bag in which the animal was being held prior to release. The eggs were 21.2 × 10.1 mm; 23.1 × 9.6 mm; 23.7 × 9.7 mm and 24.7 × 9.1 mm. An attempt was made to hatch the eggs with no success.

CONOPHIS LINEATUS (Road Guarder). **DIET**. *Conophis lineatus* is a medium-sized snake that feeds on vertebrates, especially lizards of the genus *Aspidoscelis* and rodents (Lee 1996. The Amphibians and Reptiles of the Yucatán Peninsula. Cornell Univ. Press, Ithaca, New York, 500 pp.; Wellman 1963. Univ. Kans. Publ. Mus. Nat. Hist. 15[6]:251–295). At ca. 1300 h on 13 October 1996 on Isla Mujeres Quintana Roo, México (21.2472°N, 86.7417°W), one of us (OH-G) observed a *C. lineatus* on a sand beach below a shrub (*Suriana maritima*). The snake was in the process of constricting a juvenile *Ctenosaura similis*, which was later ingested head first (photographic vouchers, CNAR-RF 21 a–b).

CROTALUS ADAMANTEUS (Eastern Diamond-backed Rattlesnake). **PREY**. Known prey items for *C. adamanteus* include rodents, squirrels, rabbits, and a few species of birds. The latter group includes several passerines, Northern Bobwhite (*Colinus virginianus*), juvenile Wild Turkey (*Meleagris gallopavo*), and Pileated Woodpecker (*Dryocopus pileatus*) (Timmerman 1995. Bull. Florida Mus. Nat. Hist. 37:127–158; Timmerman and Martin 2002. Herpetol. Circ. 32:1–70; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 668 pp. and references therein; D. B. Means, pers. comm.). We note here another species of passerine bird captured by *C. adamanteus* in the field and one accepted in captivity.

At 0700 on 4 October 2007 one of us (CR) found a *C. adamanteus* (ca. 1500 mm TL) lying under a 60 cm^2 wooden feeding platform in a 2.4 × 7.3 m welded wire chicken coop on the north end of Cumberland Island, Camden County, Georgia (30.9226°N, 81.4361°W) that was eating an adult Cardinal (*Cardinalis cardinalis*). The habitat adjacent to the coop has an open canopy of pecan trees and a sparse understory that is part of a small settlement of houses. The snake had apparently killed but did not eat a 2/3 grown domestic chicken the day before. Upon discovery, the adult male Cardinal was in the same place as the chicken and being swallowed by the snake. The snake finished swallowing the bird in a plastic cooler after capture. It also ate a dead Carolina Wren (*Thryothorus ludovicianus*) offered to it in a cage on 16 October 2007. Captive *C. adamanteus* has been reported to eat Goldfinches, Chipping Sparrows, and warblers in captivity (Williams 1892. Science 20:345). Our observations add one new species of bird to the natural diet of this rattlesnake (Cardinal) and one new species accepted by a captive individual (Carolina Wren).

CROTALUS CATALINENSIS (Santa Catalina Island Rattlesnake). **ARBOREALITY**. *Crotalus catalinensis* is generally considered an adept climber (Grismer 2002. Amphibians and Reptiles of Baja California, Including Its Pacific Islands and the Islands in the Sea of Cortés, University of California Press, Berkeley, California. 409 pp.), however, there are few data to support this assumption. Here I present field observations that corroborate the presumed proclivity for arboreality. During an ecological study in 2003–2004 we visited Santa Catalina Island on seven occasions: thrice between March and June (dry season), and four times between July and October (rainy season). We spent a total of 276 person-hours searching for snakes over 32 days. We searched for snakes between 1900 and 2400 h and recorded sex, snout–vent length (SVL), color phase, place of capture (on ground or on vegetation) and height above ground level. Seventeen of 45 *C. catalinensis* were found on vegetation during the dry season and three of 159 were found on vegetation in the rainy season. Of the twenty snakes (mean SVL = 527 ± 128 mm, range = 276–733 mm, N = 20) found on vegetation, twelve were males and eight were females, and of these, eleven were gray phase and nine were brown phase. Mean height above ground level was 36 ± 19 cm (range = 10–75 cm). Plant species used included Cardon Cactus (*Pachycereus pringlei*; N = 5), Copal (*Bursera hindsiana*; N = 4), Elephant Tree (*Bursera microphylla*; N = 3), Palo Verde Tree (*Cercidium microphyllum*; N = 2), Cholla Cactus (*Opuntia cholla*; N = 1), Jojoba (*Simmondsia chinensis*; N = 1), and four not registered.

According to Klauber (1982. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. University of California Press, Berkeley. 350 pp.) this behavior is common among some rattlesnakes and can be related to foraging activities. Santa Catalina Island Deer Mice (*Peromyscus slevini*), the main prey of *C. catalinensis* (Avila-Villegas et al. 2007. Copeia 2007:80–84), are also frequently found climbing in shrubs (pers. obs.), lending credence to the notion that *C. catalinensis* uses vegetation as hunting sites. However, I have also observed *C. catalinensis* traveling considerable distances (e.g., 3.0 m) in a straight line through vegetation at heights of 0.6 m in January 2005 (Avila-Villegas 2006. Herpetol. Rev. 37:476), which may suggest that frequent presence in vegetation is due to transit upon it.

I thank G. Arnaud, M. Martins, F. Torres, N. Villalejo, C. Venegas, V. Ortíz, J. Navarro, A. Tejas, A. Cota, M. Villarejo, F. Cota, S. Avila, E. Zarza, M. Mainers and M. A. Leal for assistance.

CROTALUS MOLOSSUS NIGRESCENS (Mexican Black-tailed Rattlesnake). **BEHAVIOR.** Snakes present a broad variety of defensive behaviors when confronted with potential predators. The most common include fleeing, vibrating the tail, gaping the mouth, cloacal discharge, hissing, and biting (Martins 1996. Anais de Etologia 14:185–199). Some elapids gape their mouths and spit venom at potential predators (Young et al. 2004. J. Exp. Biol. 207:3483–3494). Anti-predator behaviors also vary with the level of menace perceived by the snake (Whitaker and Shine 1999. Wildl. Res. 26:689–704). Herein, we report venom spitting by *Crotalus molossus.*

On 12 January 2005, at the Laboratory of Biodiversity (Dirección General de Divulgación de la Ciencia-Universidad Nacional Autónoma de México), an adult *C. molossus* (890 mm SVL) was temporarily placed in a plastic container, while its cage was cleaned. When the snake was returned to its cage it adopted a defensive posture, arching the body in an "S" form, opening the mouth widely, and hissing loudly. Immediately, the handler (CAMS) moved approximately a meter away. The snake lunged forward with its mouth agape and ejected venom into the handler's eyes, resulting in a feeling of intense heat and momentary blindness over the course of the next 3 min. The handler's eyes were immediately flushed with copious amounts of water and over the remainder of the day the handler didn't present any other symptoms. However, at ca. 0730 h the next morning, the handler experienced nausea, tachycardia, and a decrease of arterial pressure. He also fainted several times over a period of ca. 5 min. Under medical supervision, the patient was treated with Meticortelone® corticosteroid and completely recovered over the course of seven days.

Current evidence suggests that the ability to spit venom has evolved multiple times within the cobras (Wüster 1996. Toxicon 34:399–406; Keogh 1998. Biol. J. Linn. Soc. 63:177–203). Multiple appearances of this defensive behavior in the evolutionary history of elapids suggests it has broad adaptive value. While this observation appears to be an isolated observation, it may represent a latent behavior in Crotalidae that presents irregularly or only under certain conditions. Interestingly, one of us (CJBV) has observed similar behavior in *Crotalus atrox*. Alternatively, agitated pitvipers might accidentally and prematurely eject venom in some circumstances.

Submitted by **CARLOS AUGUSTO MADRID SOTELO** (e-

mail: madridherp@aol.com) and **CARLOS JESÚS BALDERAS VALDIVIA** (e-mail: cjbv@servidor.unam.mx), Laboratorio de Biodiversidad, Dirección General de Divulgación de la Ciencia, Universum, UNAM, Zona Cultural Universitaria, CP 04510, México, D.F.

CROTALUS RAVUS (Mexican Pygmy Rattlesnake). **DIET**. There are few reports regarding the feeding habits of *Crotalus ravus*. However, lizards (*Sceloporus grammicus*, *S. megalepidurus*), mammals (*Mus musculus*, *Microtus mexicanus*), and insects (Hemiptera and Orthoptera) have been reported in the diet of this species (Uribe-Peña et al. 1999. Anfibios y Reptiles de las Serranías del Distrito Federal, México. Instituto de Biología, Universidad Nacional Autónoma de México. 119 pp.; Mendoza-Hernández et al. 2004. Herpetol. Rev. 35:63).

In May 2001 we found a *C. ravus* at the base of a cactus (*Opuntia* sp.) near La Preciosa Lake (19.3678°N, 97.3867°W, WGS84; 2040 m), Las Minas, Puebla State, México. The snake was eating an adult *Sceloporus spinosus*. Photographic vouchers (MZFC 1604–05) are in the Herpetological Collection of Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México.

Furthermore, on 12 May 2007 we collected an adult female *C. ravus* (167 mm SVL, 186 mm TL), in Delegación Magdalena Contreras (19.2879°N, 99.2670°W, WGS84; 2580 m) in the southern mountains of Distrito Federal, México. The specimen (MZFC 20902) was found crossing a trail in oak forest. A fragment of a snake tail was found in the snake's stomach. We identified the prey as *Thamnophis scalaris*, by comparing the tail fragment to the tails of other snakes collected in the same area. This is the first report of a snake in the diet of *C. ravus*.

We thank Manejo de Ecosistemas y Desarrollo Humano, Universidad Nacional Autónoma de México (SDEI-PTID-02) for financial support.

Submitted by **ISRAEL SOLANO-ZAVALETA** (e-mail: crotalus.viper@gmail.com), **URI OMAR GARCÍA-VÁZQUEZ** and **MARTHA L. CALDERÓN-ESPINOSA,** Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, Apartado Postal 70-399, México, Distrito Federal 04510, México.

EUNECTES MURINUS (Green Anaconda). **LONGEVITY**. Anacondas and other large reptiles tend to live many years and grow slowly later in life. However, long-term data on growth rates for wild snakes are in short supply. Here we report recapture of a *Eunectes murinus* after 13 years. These observations were made in the course of conducting an on-going mark-recapture project (running since 1992) in the Venezuelan llanos, Distrito Muñoz, Apure State (7.5ºN, 69.3ºW). All snakes were marked using scale clipping and by copying the ventral pattern covering the first 15 subcaudal scales (Rivas et al. 2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 128–138. Eagle Mountain Publishing Company, Eagle Mountain, Utah).

On 27 August 1994 we captured a female (E548, 324 cm SVL, 21 kg). Thirteen years later on 19 March 2007, we caught E548 again and although the scale clipping mark was difficult to read, we were able to identify the individual unequivocally by comparing the subcaudal pattern with our records. Upon recapture E548 measured 366 cm SVL and 25 kg. E548 was wounded, weakened, and had a subcutaneous nematode (possibly *Dracunculus* sp.) which has been found in other individuals in this population (Calle et al. 1994. J. Zoo. Wild. Med. 25:53–64).

This may be the longest recapture record of any individual snake in the wild. Twelve-year recaptures have been reported by Madsen and Shine (2000. J. Anim. Ecol. 69:952–958). It is surprising that in 13 years E548 only grew 42 cm. It is expected that the growth rate of large reptiles will decrease towards older age (e.g., Madsen and Shine, *op. cit*.), but E548 is still far from the largest size recorded for this region (exceeding 500 cm, Rivas et al., *op. cit*.) and even further from other literature records. Cursory evaluation of our mark/recapture data suggest that anacondas in the wild may take more than a decade to reach 320 cm SVL, so E548 could be in her mid-twenties or perhaps even older.

The harvest of anacondas have been present for more than two decades driven largely by demand for luxury snakeskin products in the global market (Waller et al. 2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 340–362. Eagle Mountain Publishing Company, Eagle Mountain, Utah). However, rural populations may also be increasing their harvest in response to changes associated with macroeconomic packages that are affecting much of South America (Rivas 2007. Iguana. 14:10–21). Nevertheless, a recent three-year study monitored the experimental harvest of wild *Eunectes noteus* (Yellow Anaconda) and concluded that harvest could be sustainable based primarily on high reproductive rates, large distribution, and low human density (Waller et al., *op. cit.*). However, if the extremely slow growth rate presented here is the norm, we believe that the notion of sustainability is suspect in regions with high harvest/mortality (see Rivas, *op. cit*.; Rivas et al. 1999. Herpetol. Rev. 30:101; Rivas 2000. Unpubl. Ph.D. dissertation, University of Tennessee. 287 pp.; Rivas et al. 2001. Herpetol. Rev. 32:107–108).

We thank the Wildlife Conservation Society, Zoo de Doue la Fontaine-France, Miami Metro Zoo, Anaconda Investments LLC, COVEGAN, J. and T. Dunbar, and T. Hughes for assistance.

COREY**, Department of Evolution, Ecology, and Organismal Biology, The Ohio State University, 318 W. 12th Avenue, Columbus, Ohio 43210, USA.

FARANCIA ABACURA (Mud Snake). **PREDATION**. Few records exist regarding predators of *Farancia*. Palmer and Braswell (1995. Reptiles of North Carolina. University of North Carolina Press, Chapel Hill) reported that American Alligators (*Alligator mississippiensis*) and Cottonmouths (*Agkistrodon piscivorus*) consumed *Farancia abacura* and these appear to be their only documented predators. It has been suggested that birds of prey and wading birds predate mud snakes (Ernst and Ernst 2004. The Snakes of the United States and Canada. Smithsonian Press, Washington, D.C.) and birds have been used experimentally to elicit death feigning (Doody et al. 1996. Herpetol. Rev. 27:82–83). However, there are no records of birds preying upon Mud Snakes *in situ*.

On 2 March 2008 at ca. 1830 h a Barred Owl (*Strix varia*) was observed attacking a juvenile *F. abacura* (238 mm SVL, 6.8 g) on a road at Lake Martin, St. Martin Parish, Louisiana, USA (30.214°N, 91.898°W). The owl fled when approached leaving the snake behind. The snake was collected alive without conspicuous external injuries although it expressed a slow righting response and locomotor difficulties. The snake died approximately one hour later. Ambient temperature was 20.9°C with 59% humidity.

LAMPROPELTIS TRIANGULUM (Milksnake). **DIET**. Although *L. triangulum* is known to prey on snakes, *Arizona elegans* (Glossy Snake) has not been previously reported as prey (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp; Williams 1978. Systematics and Natural History of the American Milksnake, *Lampropeltis triangulum*. Milwaukee Public Mus. Publ. Biol. Geol. [2]:1–258). At 2355 h on 1 June 2006, we encountered an adult male *L. triangulum* (622 mm SVL, 63 mm tail, 83 g) in the process of swallowing an adult female *A. elegans* (561 mm SVL, 89 mm tail, 61 g) that was 74% of its mass at the Caprock Wildlife Area, Chaves County, New Mexico, USA (33.4541667°N, 103.7923611°W, WGS84). We monitored this interaction from discovery to complete ingestion which occurred at 0130 h on 2 June 2006. This is the first documentation of *L. triangulum* preying on *A. elegans*. Both individuals were collected and deposited in the University of New Mexico Museum of Southwestern Biology (MSB 72600, 72601).

FIG. 1. Adult male *Lampropeltis triangulum* ingesting an adult female *Arizona elegans*. Chaves County, New Mexico. Photo taken on 1 June 2006.

PAINTER**, New Mexico Department of Game and Fish, Endangered Species Program, 1 Wildlife Way, Santa Fe, New Mexico 87507, USA.

LAMPROPELTIS TRIANGULUM TRIANGULUM (Eastern Milksnake). **DICEPHALISM.** A dicephalic neonate *Lampropeltis triangulum* collected 26 September 2004 by Glen Tricarico beneath a rock in a rock wall surrounding a backyard in Winthrop, Maine (44.3356°N, 69.9850°W) measured 200 mm total length (TL) and weighted 4.0 g. The snake shed for the first time on 7 October 2004. Since then it has shed 35 times and currently measures 735 mm TL and weighs 98 g. After continued refusal of various invertebrate prey, it readily fed upon *Scincella lateralis* on 5 November 2004. It was weaned onto pinkie mice for its second meal and has eaten 303 since then. Of those feedings, 200 were by the right head and 103 by the left. Initially both heads fought over food but they have learned to cooperate in feeding.

Previously published records of dicephaly in *L. triangulum* include Bancroft (1769. An Essay on the Natural History of Guiana, in South America. Becket and De Hondt, London, 214 pp.) for a New York specimen, W. Smith (1882. Rep. U.S. Geol. Surv. Ohio 4:690) for a Michigan specimen, Blatchley (1906. Proc. Acad. Nat. Sci. Philadelphia 58:421) for an Indiana specimen, Hyde (1925. Natural History 25:187) for another New York specimen, and Ernst (1960. Trans. Kentucky Acad. Sci. 26:67) for a Pennsylvania specimen. This is the sixth documented case of *L. triangulum* although three unverified reports exist (Cunningham 1937. Axial Bifurcation in Serpents. Duke Univ. Press, Durham, North Carolina. 91 pp.).

Submitted by **VAN WALLACH,** Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts 02138, USA; e-mail: vwallach@oeb.harvard.edu.

LEPTODEIRA ANNULATA **(**Banded Cat-Eyed Snake). **DIET.** *Leptodeira annulata* is a nocturnal, arboreal colubrid snake which habits primary and secondary forests (Vitt 1996. Herpetol. Nat. Hist. 4:69–76). The dissection of 260 *L. annulata* specimens originally collected in southeastern and midwestern Brazil and deposited in the Instituto Butantan (IB) collection, revealed 22 prey items consumed by 17 snakes (three individuals consumed two prey each and one individual consumed three). Hylid, leptodactylid, and bufonid anurans constituted 77% of these prey items. Other identified prey include one *Hemidactylus mabouia* (ingested by a 449 mm SVL juvenile female), beetles and plant material (probably ingested incidentally), and two colubrid snakes. The colubrids were an *Atractus zebrinus* (318 mm SVL, 41 mm tail length [TL]) consumed by a female *L. annulata* (612 mm SVL, 25.1 mm head length [HL]) and an *Oxyrhopus guibei* (195 mm SVL, 55 mm TL) consumed by a male *L. annulata* (526 mm SVL, 19.7 mm HL). Prey were consumed head-first excepted by the *A. zebrinus*, which was consumed tail first. Our observations are consistent with previously published data suggesting that anurans comprise the majority of prey items consumed by this species (Martins and Oliveira 1999. Herpetol. Nat. Hist. 6:78–150) and that small lizards can be occasionally eaten as well (Amaral 1978. Serpentes do Brasil. Iconografia colorida. Melhoramentos/Univ. São Paulo, Brazil; Vitt 1996. Herpetol. Nat. Hist. 4:69–76; Cunha and Nascimento 1978. Ofídios da Amazônia. Museu Paraense Emilio Goeldi, Brazil). However, these are the first records of ophiophagy in this species. *Atractus zebrinus* is a terrestrial and fossorial snake, sympatric with *L. annulata* while *O. guibei* is a terrestrial snake which inhabits semi-deciduous forests, open,

and disturbed areas. There are no records of *O. guibei* in the area where *L. annulata* was collected. This suggests that *O. guibei* may have been consumed opportunistically after its collection while transported with other snakes or even in the captivity if it was kept with other specimens before it was preserved. Furthermore, our data suggest that this arboreal snake may forage both on the vegetation and on the ground.

Submitted by **MAURÍCIO CANTOR** and **LÍGIA PIZZATTO**, Universidade Estadual de Campinas, Departamento de Zoologia, CP 6109, 13083-970, Campinas, SP, Brazil (e-mail: maucantor@gmail.com).

MASTICOPHIS MENTOVARIUS (Neotropical Whipsnake). **ATTEMPTED PREDATION AND DIET.** *Masticophis mentovarius* is a large diurnal species distributed from Sonora, México to Colombia (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas, University of Chicago Press, Chicago. 934 pp.). Little is known regarding the biology of northern populations and few predators or predatory attacks have been documented for the species.

On 1 August 2005 at 2219 h we observed a large adult (ca. 1070 SVL) Common Kingsnake (*Lampropeltis getula*) writhing on the road after being struck by a passing vehicle near Navajoa, Sonora. A large section of snake's gut was exposed revealing the partially digested remains of a recently consumed juvenile *M. mentovarius*.

On 3 August 2005 at 2249 h we observed a large adult *M. mentovarius* (ca. 1700 mm SVL) crawling rapidly onto a paved road between Navajoa and Minas Nuevas, Sonora. Upon stopping, we noticed the snake being chased by a small adult American Badger (*Taxidea taxus*). The badger repeatedly bit the snake and in one instance shook it at mid-body. Our presence caused the badger to retreat into the vegetation. Upon inspection we noticed that the snake was injured and bleeding from several sections of its body. The snake contained a large food bolus, which might have hindered its escape. The snake voluntarily regurgitated the prey item, an adult Norway Rat (*Rattus rattus*).

Masticophis mentovarius has been reported as a prey of both the Great Black Hawk (*Buteogallus urubitinga*) in Guatemala (Gerhardt et al. 1993. Biotropica 25:349–352), and the White Tailed Hawk (*Buteo albicaudatus*) in Colombia (Smith 1942. Copeia 2:85–88). Our observations provide novel information regarding the predators of this species in Sonora, Mexico.

Submitted by **ERIC A. DUGAN** (e-mail: edugan1@hotmail.com) and **ALEX FIGUEROA** (e-mail: afigueroa21@gmail.com), Department of Earth and Biological Sciences, Loma Linda University, Loma Linda, California 92350, USA.

MICRURUS BRASILIENSIS (Brazilian Coralsnake). **DIET.** On 7 January 2005 we found what we believe to be an *Apostolepis assimilis* (500 mm SVL, 40 mm TL, 15 g) in the stomach of a DOR adult *Micrurus brasiliensis* (610 mm SVL, 40 mm TL, 32 g) collected at Fazenda Floryl (13.95ºS 46.01ºW), near the municipality of Correntina, Bahia. Specific identification of the prey species was not possible as the head was missing. The snakes were deposited in the Coleção Herpetológica da Universidade de Brasília, Brasília, Brazil (*M. brasiliensis* - CHUNB 39081 and *A.* cf. *assimilis* - CHUNB 39079). Martins and Oliveira (1998. Herpetol. Nat. Hist. 6:78–150) recorded predation of *Apostolepis* sp. by *Micrurus spixii* in Manaus region, Central Amazon, Brazil. However, our observation is the first record of *Apostolepis* in the diet of *M. brasiliensis.*

We thank F. Floryl/Jatobá and D. F. Silva for assistance.

Submitted by **ADRIANA BOCCHIGLIERI**, Programa de Pós-graduação em Ecologia, Universidade de Brasília, 70910-900, Brasília, DF, Brazil (e-mail: adriblue@hotmail.com); and **MARCELO LIMA REIS**, Diretoria de Conservação da Biodiversidade/ICMBio, 70818-900, Brasília, DF, Brazil.

MICRURUS CORALLINUS (Painted Coralsnake)**. DIET.** *Micrurus corallinus* is a fossorial and diurnal coralsnake that ranges from Rio Grande do Norte to Rio Grande do Sul states in Brazilian Atlantic Forest (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York). This species feeds primarily on elongate ectothermic prey such as snakes, lizards, and amphisbaenians (Cunha and Nascimento 1978. Mus. Par. Emílio Goeldi Publ. Avuls. 31:1–218; Marques and Sazima 1997. Herpetol. Nat. Hist. 5:88–93).

On 27 May 2007 at 1230 h, I observed an adult male of *M. corallinus* (MNRJ 15119; 430 mm SVL, 31 mm tail length [TL]) feeding on an adult male *Tantilla melanocephala* (Crowned Snake; MNRJ 15120; 205 mm SVL, 62 mm TL) above a rock at Boqueirão, Pontal do Atalaia, Arraial do Cabo, Brazil (22,5899°S, 41,9999°W, 28 m elev.). The *M. corallinus* was swallowing the *T. melanocephala* headfirst before I interrupted. Marques and Sazima (*op. cit*.) reported a positive correlation between prey total length and predator SVL in *Micrurus corallinus*. Prey length ranged from 21–93% of the snake SVL. This is the first record of *M. corallinus* preying on *T. melanocephala*.

Submitted by **ROBERTA R. PINTO**, Departamento de Vetebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Quinta da Boa Vista, s/n, 20940-040, São Cristóvão, Rio de Janeiro, Rio de Janeiro, Brazil; e-mail: robertarich@gmail.com.

NERODIA SIPEDON (Northern Watersnake). **MORTALITY CAUSED BY MUSSEL.** Interactions between freshwater mollusks and aquatic vertebrates are not uncommon. Freshwater bivalves are prey items for many vertebrates (muskrats, fish, turtles, etc.) and many freshwater mollusks have larval stages that parasitize vertebrates. Freshwater mussels of the family Unionidae have larvae, "glochidia," which are ectoparasites on vertebrates, generally fish species although one species parasitizes the Mudpuppy, *Necturus maculosus* (Parmalee and Bogan 1998. The Freshwater Mussels of Tennessee. The University of Tennessee Press, Knoxville, Tennessee. 328 pp.). Freshwater mussels have evolved different methods of attracting their host to increase their reproductive success, the most dramatic example being species that produce an extension of their mantle that resembles small fish, complete with eye-spots and tails. Furthermore, brooding freshwater mussels will flap and wave these mantle displays to mimic

FIG. 1. *Nerodia sipedon* caught in grasp of a Rabbitsfoot Mussel, *Quadrula cylindrica*.

fish movements, all the while attracting the piscivorous fish that are the host for their larvae (Haag and Warren 1999. Freshwater Biol. 41:1–6). However, these species interactions rarely end in the death of the vertebrate.

On 13 July 2006 we found a *Nerodia sipedon* that might have attempted to strike at a displaying rabbitsfoot mussel (*Quadrula cylindrica)* at a site in the Little River in southeast Oklahoma, USA. The snake's jaw was caught in the grasp of the mussel's valves (Fig. 1), and the snake was dead, likely from drowning in the several inches of water where they were found. Given that *Q. cylindrica* larvae parasitize small fish in the genus *Cyprinella*, and that they have been reported to brood larvae and display from May to July (Parmalee and Bogan 1998, *op. cit.*), we believe that the mussel's display behavior was in part responsible for the snake's death. Because northern *N. sipedon* are known to feed on small fish (Sievert and Sievert 1993. Reptiles of Oklahoma. Oklahoma Department of Wildlife Conservation, Oklahoma City, Oklahoma. 104 pp.), we think it is possible that the snake was striking at a fish that was attracted to the displaying mussel. Alternatively, the snake could have thought that the mussel's display itself was an appropriate food item, and struck at the display. Somewhat less likely is the possibility that the snake thought the whole mussel could have been its prey. When any foreign object is thrust into the opening of a mussel shell, the mussel almost always closes its valves. To our knowledge this is the first report of a snake being killed by a mussel and the first time any of us have seen anything like this in our 30+ years of experience of field work in rivers and streams.

We thank the Oklahoma Department of Wildlife Conservation for financial assistance.

Submitted by **DANIEL C. ALLEN** (e-mail: dallen@ou.edu), **DANE M. MORRIS**, and **CARYN C. VAUGHN,** Oklahoma Biological Survey, University of Oklahoma, 111 E. Chesapeake Street, Norman, Oklahoma 73069, USA.

NERODIA TAXISPILOTA (Brown Watersnake). **DIET**. *Nerodia taxispilota* is known to feed primarily on fish, particularly catfish (Ictaluridae; Camp et al. 1980. J. Herpetol. 14:301–304). Herein, we report *N. taxispilota* feeding on an invasive catfish previously undocumented as a prey species.

On 17 May 2007 at 1730 h, one of us (AT) observed an adult *N. taxispilota* (ca. 80 cm total length) on the bank of the Ichawaynochaway Creek at the Joseph W. Jones Ecological Research Center, Baker County, Georgia, USA. The snake was holding the anterior end of a live *Pylodictis olivaris* (Flathead Catfish, ca. 20 cm TL). Over the course of ca.1 h, the *N. taxispilota* swallowed half the catfish. *Pylodictis olivaris* is an introduced invasive in the Flint River and its tributaries, including Ichawaynochaway Creek.

Submitted by **ALEX TYSON, DAVID A. STEEN**, and **LORA L. SMITH**, Joseph W. Jones Ecological Research Center, Route 2 Box 2324, Newton, Georgia 39870, USA (e-mail: LexTyson@AOL.com)

PLIOCERCUS ELAPOIDES AEQUALIS (Variegated False Coralsnake). **DIET.** *Pliocercus elapoides* is a wide ranging and variable mimic of venomous coralsnakes. It inhabits rainforest and cloud forest slopes in México and Central America.

On 24 June 2007 at 0900 h we observed a male *P. elapoides aequalis* (287 mm SVL, 496 mm total length) feeding on a ca. 28 mm SVL *Gastrophryne elegans* (Microhylidae; Elegant Narrow-mouthed Toad). The observation was made on a narrow dirt path at the edge of tropical rainforest near Laguna Escondida, Los Tuxtlas, Veracruz, Mexico (18.5908ºN, 95.0882°W, 150 m elev., WGS84). The snake held the anterior body portion of the dead frog inside its mouth and spent ten minutes to swallow it completely. The event was photographed and the snake was measured and released.

It is known that *P. elapoides* feed on amphibians. Stuart (1948. Misc. Publ. Mus. Zool. Univ. Michigan 69:1–109) and Duellman (1963. Univ. Kansas Publ. Mus. Nat. Hist. 15:205–249), mentioned that in Guatemala *P. elapoides* diet consists of salamanders of the genus *Bolitoglossa*. Also, Seib (1985. Unpubl. Ph.D. dissertation, Univ. California, Berkeley. 229 pp.) reported *Bolitoglossa* and *Eleutherodactylus* parts and terrestrial amphibian eggs in Chiapas (southern México) and adjacent Guatemala as stomach contents. This is the first record of *Gastrophryne elegans* in the diet of this species.

Submitted by **ELISA CABRERA-GUZMÁN, MARCO ANTONIO MÁRQUEZ,** and **VÍCTOR HUGO REYNOSO,** Colección Nacional de Anfibios y Reptiles, Instituto de Biología, Departamento de Zoología, Universidad Nacional Autónoma de México, Circuito exterior, Ciudad Universitaria, México D.F., C.P. 04510 (e-mail: anfisbenido@yahoo.com).

SIPHLOPHIS COMPRESSUS (Red-eyed Liana Snake)**. CANNIBALISM.** *Siphlophis compressus* is a rare, primarily nocturnal and often arboreal forest colubrid occurring from Costa Rica south to Brazil, including Trinidad (Martins and Oliveira 1999. Herpetol. Nat. Hist. 6:78–150; Boos 2001. Snakes of Trinidad and Tobago. Texas A&M University Press, College Station, Texas; Solórzano 2005. Snakes of Costa Rica. Instituto Nacional de Biodiversidad, Costa Rica). Data on the diet of *S. compressus* indicate that the species is primarily a lizard specialist

(Cunha and Nascimento 1993. Boletim do Museu Paraense Emilio Goeldi 9:1–191; Martins and Oliveira, *op. cit.*), and there have been no previous reports of *S. compressus* consuming snakes of any species. In this note, we report the first case of *S. compressus* preying upon another snake, and the first case of cannibalism for this species.

On 30 January 2007 at ca. 1000 h, on the Soconusco Estate, Santa Cruz, Trinidad and Tobago (10.716°N, 61.483°W), we observed two *S. compressus* among leaf litter in a forested area dominated by Balisier (*Heliconia bihai*). One snake (ca. 1 m total length) was in the last stages of ingesting another, similarly sized conspecific. A dead, apparently regurgitated *Anolis* sp. (ca. 15–20 cm total length) was ca. 1.5 m from the two *S. compressus*.

Although the initial interaction between the snakes was not observed, it is likely that this observation was a case of accidental cannibalism. *Anolis* are a common prey item for *S. compressus* (Cunha and Nascimento, *op. cit;* Martins and Oliveira, *op. cit.*) and it may be that one *S. compressus* encountered the other while in the process of ingesting the lizard, eventually resulting in accidental cannibalism.

We thank H. W. Greene for assistance.

Submitted by **JAHSON B. ALEMU I.**, 827 East 2nd Street Crescent, Edinburgh 500, Chaguanas, Trinidad and Tobago (e-mail: jahsonb@gmail.com); and **JODI J. L. ROWLEY**, Conservation International Indo-Burma, PO Box 1356, Phnom Penh, Cambodia (e-mail: jodi.rowley@gmail.com).

SISTRURUS MILIARIUS BARBOURI (Dusky Pigmy Rattlesnake). **DIET**. *Sistrurus miliarius* has been recorded feeding on frogs, lizards, snakes, small mammals and birds, insects, spiders, and centipedes (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Comstock Publishing Associates, Ithaca and London, 898 pp.; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, 668 pp.). Only the Western Pigmy Rattlesnake (*S. m. streckeri*) is known to feed on shrews (*Blarina brevicauda*) (Jacob 1981. Report for the Tennessee Wildlife Resources Agency (project #E-1-2). Herein, we document *S. m. barbouri* consuming Short-tailed Shrews (*Blarina carolinensis*).

Two *Sistrurus m. barbouri* (UF 146057, 23.0 cm snout–vent length [SVL], 3.1 cm tail length [TL]; UF 146951, 49 cm SVL, 7.5 cm TL) were collected DOR on 27 October 1985 and 4 March 1987, respectively, on Long Pine Key, Research Road, 0.5 km E of the Daniel Beard Research Center in Everglades National Park (25.3893°N, 80.6742°W, datum: WGS84; elev. < 1 m). Both of these snakes had a single *B. carolinensis* in their stomach, augmenting diet data for this native species in Florida.

Submitted by **SCOTT L. TRAVERS, KENNETH L. KRYSKO, SARAH J. ALLRED,** and **LUIS R. TIRADO,** Florida Museum of Natural History, Division of Herpetology, University of Florida, Gainesville, Florida 32611, USA.

SISTRURUS MILIARIUS MILIARIUS (Carolina Pigmy Rattlesnake) **MORPHOLOGY**. On 28 August 2005 at 1839 h I found a newborn *Sistrurus miliarus miliarius* (127 mm SVL, 152 mm total length, 4 g) crossing an asphalt road in Chesterfield County, South Carolina. The snake's head appeared short and the eyes appeared to be incompletely developed and bulged out laterally. Some features appeared normal; the pit and naris were present. Although a superficial examination suggested that this might be a case of brevicephaly (shortening of the skull), this was merely an illusion created by a head that is disproportionately wide across the eyes. The specimen's head measured 12.1 mm from the snout to the posterior margin of the jaws. Head length of the specimen is 8.2% of the total body length, which is not remarkably different from six other juvenile specimens that I measured (mean = 8.3%). The width of the head, across the eyes, measured 11.3 mm. On the other juveniles I measured, a line transecting the venom glands represented the widest part of the head and the average width across the eyes was 86% of the width across the venom glands. In the present case, the width of the head across the eyes was 136% of the width across the venom glands. Furthermore, head width (across the eyes) on the typical juveniles averaged 52.8% of head length. On this specimen, the width of the head across the eyes is 93.4% of the head length. The snake is deposited in the North Carolina Museum of Natural Sciences (NSM 68554).

FIG. 1. Juvenile *Sisturus miliarus miliarius* with abnormal head morphology.

STILOSOMA EXTENUATUM (Short-tailed Snake). **DIET AND PREDATION**. *Stilosoma extenuatum* is known to feed on small, smooth-scaled colubrid snakes and rarely on lizards, both in the wild and in captivity (Rossi and Rossi 1993. Herpetol. Rev. 24:100–101, and literature cited therein]. On 14 March 2007, a partially eaten (tail and posterior to gall bladder), adult *S. extenuatum* was found in the garage at 4085 Ramona Drive, Spring Hill, Florida. The snake appeared to have been killed by a dachshund. Gut contents of the snake contained a partially digested, adult *Ramphotyplops braminus* (Brahminy Blind Snake), the first record of this introduced typhlopid in the diet of *S. extenuatum* and a new county record for *R. braminus*. Both specimens were deposited in the National Museum of Natural History under the same catalog number (NMNH 563619).

Submitted by **J. STEVE GODLEY**, **SHANNON M. GONZALEZ**, and **MARY C. GONZALEZ**, Biological Research Associates, 3905 Crescent Park Drive, Riverview, Florida 33578, USA.

TANTILLA GRACILIS (Flathead Snake). **COURTSHIP**. *Tantilla gracilis* is a small, semi-fossorial, saxicolous snake that occurs in Arkansas, Kansas, Louisiana, Missouri, Oklahoma, Texas, and southwestern Illinois (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. University of Arkansas Press, Fayetteville). In Louisiana and Texas, most individuals are collected from beneath rocks in spring or early summer, with gravid females found in June and July and oviposition (clutch size of 2–3 eggs) occurring in these months (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana State University Press, Baton Rouge; Cobb 1990. Southwest. Nat. 35:222–224). Relatively little is known about courtship in this species or when it occurs.

On 15 March 2008 at 1530 h CST, we captured an adult male (157 mm total length) and female (226 mm total length) together beneath a large sandstone rock (50 x 25 x 6 cm) in the Kisatchie Ranger District of Kisatchie National Forest, Natchitoches Parish, Louisiana (31.476611°N, 93.076361°W, 34 m elev., WGS84). The male was lying in a loose coil on top of the female with the posterior third of his body partially intertwined with hers. The vegetation of this habitat is dominated by Longleaf Pine and the area is actively managed for Red-cockaded Woodpeckers and had been recently burned (within a week of our observation). The terrain had a moderate slope, the ground was covered by a loose assortment of sandstone rocks, and there were a series of streams and springs that occurred at irregular intervals. Our observation is the first report of courtship behavior for this species and indicates that mating occurs as early as March in the southern portion of its range.

AKIN,** Department of Biological Sciences, Northwestern State University of Louisiana, Natchitoches, Louisiana 71497, USA; and **DANIEL N. PROUD,** Department of Biology, University of Louisiana at Lafayette, Lafayette, Louisiana 70504-2451, USA.

THAMNOPHIS SIRTALIS FITCHI (Valley Gartersnake). **HABITAT AND BEHAVIOR**. *Thamnophis sirtalis* is the most widely distributed snake in North America and is typically found near both lentic and lotic waters in meadows, farms, and damp woodlands up to 1800 m (Behler and King 1991. The Audubon Society Field Guide to North American Reptiles and Amphibians. Alfred A. Knopf, New York. 743 pp.). Here we describe *Thamnophis sirtalis fitchi* using the nest of *Neotoma fuscipes annectens* as a shelter.

On 27 September 2007, we disassembled four *N. f. annectens* nests in a willow (*Salix*) riparian woodland along the banks of Uvas-Carnadero Creek, Santa Clara County, California (36.9167°N, 121.5333°W, NAD27). From a nest built around a willow tree, we removed one adult *T. s. fitchi* and four juveniles from the lower level of the nest containing decomposing vegetation and relocated them to a leaf litter layer near the creek. Woodrat nests are probably attractive shelters and retreats for reptiles. Whereas larger snake species (e.g., *Crotalus* and *Pituophis*), might prey upon woodrats or their young while using the burrows, this is unlikely to be true of *T. sirtalis*. In this case, use of the burrows represents a commensal relationship in that the gartersnakes benefit from the use of the woodrat burrows, but the woodrats are largely unaffected by the interaction.

We thank N. R. Sisk, D. P. Newman, and S. I. Hagen for assistance. Permits and support provided by the California Department of Fish and Game, and the Santa Clara County Water District provided additional support.

Submitted by **HOWARD O. CLARK, JR.**, H. T. Harvey and Associates, Fresno, California, USA (e-mail: hclark@harveyecology.com); and **JENNIFER R. GWOREK**, H. T. Harvey and Associates, Los Gatos, California, USA.

TROPIDOPHIS WRIGHTI (NCN). **NEONATES**. On 11 April 2001 an adult female *Tropidophis wrighti* (385 mm SVL, 50 mm tail length [TL], 17 g) was found in submontane rainforest in Altiplanicie El Toldo, Moa municipality, Holguín province, Cuba (20.45°N, 74.90°W). The female was held in captivity, provided water *ad libitum*, and was fed *Anolis sagrei*, *Eleutherodactylus* spp. and small *Bufo peltocephalus*. The snake shed on 21 May and 6 August 2001. On 27 August 2001, the female gave birth to three neonates: two live (124 mm SVL, 22 mm TL and 127 mm SVL, 21 mm TL) and one dead (136 mm SVL, 21 mm TL). I could not determine if the dead neonate had died before or after parturition. Two additional yolk masses (10 x 6 mm and 9 x 6 mm) found on 8 September 2001 indicated that two additional ova failed to develop. The female's mass after parturition was 15.5 g. On 29 September 2001, another female (ca. 40 mm total length) maintained in captivity and of unknown origin, gave birth to five neonates.

Our observations of litter size in *T. wrighti* fall within the range reported for other species of this genus (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions and Natural History. Univ. Florida Press, Gainesville; Powell et al. 1992. Bull. Chicago Herpetol. Soc. 27:116–117; Fong 2005. Herpetol. Rev. 36:118–119) and neonatal sizes reported here are similar to the only other record (Fernandez and Alonso 2005. Herpetol. Rev. 36:330).

I thank Luis M. Diaz and Josefina Blanco for assistance.

Submitted by **ANSEL FONG G.**, Centro Oriental de Ecosistemas y Biodiversidad (BIOECO), Museo de Historia Natural "Tomás Romay," Enramadas #601, Santiago de Cuba 90100, Cuba; e-mail: ansel@bioeco.ciges.inf.cu.

VIRGINIA STRIATULA (Rough Earth Snake). **AGGREGATION AND URBAN HABITAT**. Snakes form aggregations in social and non-social contexts, such as courtship (e.g., Luiselli 1996. J. Zool. 239:731–740; Shine et al. 2005. Anim. Behav. 69:1251–1258), thermoregulation (Graves and Duvall 1987. Herpetologica 43:259–264), hibernation (Cobb et al. 2005. Southeast. Nat. 4:723–730), and refuge use (Gregory 2004. Herpetologica

60:178–186). Individuals of at least one species (*Crotalus horridus*) preferentially aggregate with siblings, indicating that some species may engage in complex social behavior by forming family groups (Clark 2004. Proc. Royal Soc. Biol. Sci. Ser. B 271 (Suppl. 4):S243–S245). Natricine snakes, including *Virginia striatula*, frequently exhibit complex sociality during the reproductive season. Several males may simultaneously court a single female, forming a "ball" of mating snakes (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 668 pp.). The natural habitat of *V. striatula* is typically under logs and loose bark in forests and fields; however, individuals may occur in abundance in areas disturbed by humans, such as in the plant litter of flower gardens adjacent to houses (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana St. Univ. Press, Baton Rouge. 295 pp.). Mating occurs in March and April in southern regions of its range as individuals emerge from hibernation (Dundee and Rossman, *op. cit.*).

On 11 March 2006, we observed six individual *Virginia striatula* in close spatial proximity in a highly urbanized landscape in a subdivision of Lafayette, Louisiana (30.2091ºN, 92.0755ºW). At 1900 h, we observed these and one other individual within a 2.5 x 3 m^2 area in close-cropped Bermuda grass between a sidewalk and a townhouse. The largest individual was a female (230 mm SVL, 33 tail length, 7.6 g), whereas all others were males (177–218 mm SVL, 25–44 mm tail length, 2.8–4.6 g). The subdivision was a series of town houses around which yards and public areas were maintained in short grass and manicured sidewalks. The location in which the snakes were found was across the sidewalk to a small yard maintained as a flower garden watered frequently by the owner. We assumed that these snakes use the garden as a refugium during dry conditions. The snakes were active on the surface during dry weather and appeared to be scent trailing.

We interpret the sex ratio of one female to five males, their close proximity, and apparent scent trailing behavior as a mating aggregation. The date of observation is the earliest known for reproductive behavior in Louisiana (Dundee and Rossman, *op. cit.*). This report documents that *V. striatula* populations can occupy small, highly urbanized areas if moist gardens and other landscaped areas are maintained nearby. This observation has implications for management and restoration of this small colubrid in urban habitats.

VIRGINIA VALERIAE (Smooth Earth Snake). **THREAT DISPLAY**. *Virginia valeriae* is a wide-ranging and diminutive natricine snake found in the southeastern United States (maximum reported total length: 393 mm). Many colubrid snakes, especially natricines, will gape, vibrate the tail, and eventually strike to ward off predators if unable to flee. However, it is less common to see such threat displays among small-bodied semi-fossorial or "leaf-litter" snakes, possibly because such behaviors are non-threatening and ineffectual deterrents due to the small size and lack of serious consequence to predators that results from encounters with such undersized snakes. Nevertheless, one small-bodied natricine, *Storeria occipitomaculata*, is known to exhibit an unusual threat display known as "lip-curling" when molested, whereby the lips are curled back and the teeth are revealed (Amaral 1999. J. Zool. (London) 248:289–293). A similar "lip-curling" display has also been described for one female *V. valeriae* observed in Ohio (Conant 1951. Reptiles of Ohio. Notre Dame Press). On 22 April 2007, I observed a threat display in a male *V. valeriae* (111 mm SVL) while photographing the animal *in situ* in an open canopy pine forest in the early morning in Barnwell County, South Carolina. The snake faced me and repeatedly gaped, open-mouthed, in a strike position when approached closely with the camera. During the approximate two minutes of repeated display, the snake accompanied its gaping on two occasions with lively tail vibrations that lasted 3–5 seconds. At no time did the snake strike. To my knowledge, this is the first report of a threat display involving tail-vibrations and gaping in any species of *Virginia*, a seldom reported or apparently rare behavior among small-bodied snakes. It is unclear whether this threat display is distributed more widely among species than previously assumed, is a product of phylogenetic conservatism and the natricine heritage of *V. valeriae*, or was an atypical occurrence resulting from a highly agitated individual.

WAGLEROPHIS MERREMI (False Yarara) **DIET**. *Waglerophis merremi* is a medium-sized colubrid that occurs in a variety of habitats in Argentina, Paraguay, Bolivia, Brazil, and Guayanas (Campbell and Lamar 1989. The Venenous Reptiles of the Latin America. Cornell Univ. Press, Ithaca, New York; Peters and Orejas Miranda 1970. Catalogue of Neotropical Squamata. Part. I. Snakes. Bull. U.S. Natl. Mus. 297). The majority of prey consumed by this snake are amphibians.

In Novembrer 2006 we captured and euthanized six specimens from Pago Largo (29.97ºS, 58.28ºW), Curuzú Cuatiá, Corrientes, Argentina. Dissection of the stomach and intestine showed remains of *Rhinella* (= *Chaunus*) *schneideri* (Rococo Toad) and also ribs and scales of characid fishes in one snake. The snakes and their prey were deposited in the Laboratorio de Herpetológica of the Universidad Nacional del Nordeste Argentina (UNNEC 09413, 09432–435, 09411). To our knowledge, this is the first published record of fish in the diet of *W. merremi*.

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 39, Number 1 (March 2008, p. 102). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

CAUDATA – SALAMANDERS

AMBYSTOMA LATERALE (Blue-spotted Salamander). USA: WISCONSIN: Richland Co.: Lone Rock Unit – Lower Wisconsin State Riverway (43.1815333ºN, 90.2118833ºW). 24 June 2008. Tim Muehlfeld and Mathew Muehlfeld. Photographs verified by Robert Hay (Wisconsin Department of Natural Resources-Bureau of Endangered Resources) and Gary Casper (Great Lakes Ecological Services). Illinois Natural History Survey catalogue number: INHS 2008.e. New county record. Extends range of species in Wisconsin (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum, 87 pp.). One individual captured by hand under abandoned railroad tie.

Submitted by **TIM MUEHLFELD**, We Energies, 333 W. Everett St., Milwaukee, Wisconsin 53203, USA; **MATTHEW MUEHLFELD**, 4116 Knollcrest Circle N., Martinez, Georgia 30907, USA; **JOSHUA M. KAPFER**, Natural Resources Consulting, Inc., 209 Commerce Parkway, PO Box 128, Cottage Grove, Wisconsin 53527, USA.

AMBYSTOMA MACULATUM (Spotted Salamander). USA: TEXAS: Houston Co.: 1.4 rd km SE Jct TX 21 on FR 511, Davy Crockett National Forest compartment 19 (31.55835863ºN, 95.16437ºW). 13 February 2007. Terry L. Hibbitts. Verified by James R. Dixon. Texas Cooperative Wildlife Collections, TCWC 91796. New county record and first record east of the Neches River in Texas. The specimen collected is a partial egg mass. Two egg masses were observed. (Dixon 2000. Amphibians and Reptiles of Texas. Second Ed. Univ. of Texas A&M Press, viii + 421 pp.).

EURYCEA CHAMBERLAINI (Chamberlain's Dwarf Salamander). USA: ALABAMA: Bullock Co.: Collected crossing Bullock County Rd. 35 (32.121311°N, 85.566736°W; WGS 84). 29 December 2007. S. Graham and S. Hoss. Verified by Craig Guyer. AUM 37614. Clarke Co.: Fred T. Stimpson Nature Sanctuary. In sphagnum seep draining into bay swamp tributary of Salt Creek (31.607766°N, 87.9637951°W; WGS 84). 1 February 2008. G. Sorrell and C. Raimond. Verified by Craig Guyer. AUM 37648–37649. Conecuh Co.: Collected crossing Conecuh County Rd. 106 1.9 km E of Conecuh County Rd. 29 intersection (31.707097°N, 96.925850°W; WGS 84). 20 December 2007. S. Hoss. Verified by Craig Guyer. AUM 37600. Lee Co.: Keisel Park (Lee County Rd. 51). Across nature trail from small pond (32.585351°N, 85.544435°W; WGS 84). 23 September 2008. A. Dunn. Verified by Craig Guyer. AUM 37825. Lowndes Co.: Collected crossing Lowndes County Rd. 40 (32.331481°N, 86.652537°W; WGS 84). 18 November 2007. S. Graham and K. Gray. Verified by Craig Guyer. AUM 37591–37594. Macon Co.: Tuskegee National Forest. Collected along edge of pond near intersection of Forest Service Rd. 906 and 900 (32.485284°N, 85.607894°W; WGS 84). 06 February 2002. R. Birkhead. Verified by Craig Guyer. AUM 35594. These represent the first state records of *Eurycea chamberlaini* in Alabama. Their presence in these counties suggests a fairly widespread distribution in Alabama from the Fall Line Sandhills to the Red Hills physiographic regions and a contiguous distribution from nearby populations in Georgia (Means 2008. *In* J. Jensen et al. [eds.], Amphibians and Reptiles of Georgia. University of Georgia Press, Athens and London. 595 pp.). Older range maps (Mount 1975. Amphibians and Reptiles of Alabama. Auburn University Agricultural Experiment Station, Auburn, Alabama. 347 pp.) illustrate a similar range for *E. quadridigitata* and were no doubt based on collections of both *E. quadridigitata* and *E. chamberlaini*. However, after our recent, extensive explorations of the Alabama Coastal Plain, we have only found *Eurycea quadridigitata* (*sensu stricto*) in extreme southeasternmost Alabama (Houston County). We have also found other forms of the *E. quadridigitata* complex (of uncertain taxonomic assignment) in Covington, Escambia, and Baldwin counties; identity of this form awaits detailed phylogenetic and systematic analyses which are currently underway (Means 2008, *op. cit.*).

GGS thanks J. Grand, A. Silvano, F. Pringle, and C. Nettles for logistical support. SPG thanks A. Dunn for collecting salamanders for this note and C. Guyer for verifying these records. These collection trips were supported in part by an ALDCNR SWG to J. Grand, and by NIH grant R01-A149724 to T. Unnasch, under ALDCNR Permit 4268.

HIBBITTS (**e-mail: thibbitts@tamu.edu) and **DAVID LAURENCIO,** Texas Cooperative Wildlife Collections, Department of Wildlife and Fisheries Sciences, Texas A&M University, 2258 Tamu, College Station, Texas 77843-2258, USA; **DANIEL SAENZ**, **CORY ADAMS**, and **JOSH PIERCE** Wildlife Habitat and Silviculture Laboratory, Southern Research Station, USDA Forest Service, Nacogdoches, Texas 75965, USA.

ANURA – FROGS

ACRIS CREPITANS (Northern Cricket Frog). USA: MINNESOTA: Winona Co.: Prairie Island Park at spillway of Mississippi River 5A dam (44.0789909°N, 91.6828156°W; NAD 83). 26 August 2008. Philip A. Cochran. James Ford Bell Museum (JFBM P-292-293). Verified by Kenneth H. Kozak. Multiple specimens observed along shoreline both upstream (Pool 5A) and downstream (Pool 6) of spillway. I first observed this species here on 18 September 2006, and I have heard calling males along a backwater channel across Straight Slough from this spot. Another population was located 2.4 km away (JFBM P-294-295). The recovery of a Cottonmouth (*Agkistrodon picivorus*) in this vicinity from a barge originally loaded in Louisiana (Cochran 2008. Northeast. Nat. 15:461–464) suggests the possibility that *Acris crepitans* might also have been transported north. Recent summaries of geographic distribution do not include Winona Co. (Gray et al. 2005. *In* M. J. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 441–443. Univ. California Press, Berkeley). Although some natural resource agency personnel are aware of Northern Cricket Frogs in the Winona area and their occurrence was mentioned in a newspaper article (Dankert 2006. *Winona Daily News*, Nov. 9, p. 1A), it is not clear that the species has been formally documented or that its geographic extent within the county has been assessed.

Submitted by **PHILIP A. COCHRAN,** Biology Department, Saint Mary's University of Minnesota, 700 Terrace Heights, Winona, Minnesota 55987, USA; e-mail: pcochran@smumn.edu.

ANAXYRUS FOWLERI (Fowler's Toad). USA: TENNESSEE: Campbell Co.: Norris Dam State Park (36.24461°N, 84.12098°W). 15 May 2006. John E. Copeland. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 18596). One specimen caught on Rock Creek Trail. First record for Campbell County. (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.).

HYLA VERSICOLOR / CHRYSOSCELIS **SIBLING SPECIES COMPLEX** (Gray Treefrog / Cope's Gray Treefrog). USA: TENNESSEE: Anderson Co.: 324 Bland Road, Clinton (36.14701°N, 84.10603°W). 12 June 2006. John E. Copeland. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 18596). One specimen caught on trunk of a tree. First record for Anderson Co. (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.).

Submitted by **JOHN E. COPELAND** Department of Mathematics and Natural Sciences, Lincoln Memorial University, Harrogate, Tennessee 37752, USA; e-mail: john.copeland@lmunet.edu.

HYLA VERSICOLOR (Gray Treefrog). USA: WISCONSIN: Jefferson Co.: Watertown (43.18094506°N, 88.71355654°W; NAD83, Garmin III Plus). 12 July 2008. Collected by JMK and JJK. Verified by Christopher Phillips, INHS 2008.g (MPEG video clip of calling males). Numerous males heard calling in ornamental shrubs near a commercial property. New county record, filling gap in Wisconsin distribution (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum, 87 pp.). JMK also heard calling males in a wetland ca. 0.4 km SW of this location in June 2008. A prior specimen record (MPM 16168) cataloged as "*Hyla verisicolor* complex," collected 21 May 1974 by B. Dudiak at Koshkonong, T5N R13E, could be *H. chrysoscelis*.

Submitted by **JOSHUA M. KAPFER**, Natural Resources Consulting, Inc., 209 Commerce Parkway, PO Box 128, Cottage Grove, Wisconsin 53527, USA; **GARY S. CASPER**, University of Wisconsin-Milwaukee Field Station, 3095 Blue Goose Rd, Saukville, Wisconsin 53080, USA; and **JENNIFER J. KAPFER**, 512 S. 10th St., Watertown, Wisconsin 53094, USA.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-mouthed Toad). USA: ALABAMA: Chilton Co.: 6.3 km S of CR 25 on CR 73 (33.01960°N, 87.52418°W; WGS84). 01 October 2007. J. Burling and J. Wicknick. Verified by Joseph R. Mendelson III. University of Montevallo Collection of Vertebrates (UMCV-AA0075). New county record; fills a gap among Shelby, Bibb, and Perry counties and the Coosa River (Mount 1975. The Reptiles and Amphibians of Alabama, The University of Alabama Press, Tuscaloosa. 347 pp.). Alabama Department of Conservation and Natural Resources collecting permit number 4368 (JAW).

Submitted by **JILL A. WICKNICK[1]** and **JOHN W. BURLING[2]**, Departments of Biology[1] and Psychology[2], University of Montevallo, Montevallo, Alabama 35115, USA; e-mail: wicknickja@montevallo.edu.

KALOULA PULCHRA (Painted Bull Frog). BRUNEI DARUSSALAM: BRUNEI MUARA DISTRICT: Bandar Seri Begawan,

Universiti Brunei Darussalam Campus, Gadong (4.9666667ºN, 114.8833333ºE). From a toilet. Collected by J. K. Charles. 10 January 2007. Brunei Museum (BM 2007.01). Verified by Indraneil Das. First record for Brunei Darussalam (see Das 2007. A Pocket Guide. Amphibians and Reptiles of Brunei. Natural History Publications [Borneo] Sdn Bhd. Kota Kinabalu. viii + 200 pp.). Previous Bornean records were from Sabah (Inger and Tan 1996. Raffles Bull. Zool. 44:551–574); the species generally is widespread in Southeast Asia (Inger 1999. *In* W. E. Duellman [ed.], Patterns of Distribution of Amphibians. A Global Perspective, pp. 445–482. The John Hopkins University Press, Baltimore and London). I thank Awang Mahdi bin Abdullah, Brunei Museum, for curatorial assistance.

LITHOBATES CATESBEIANUS (American Bullfrog). MALAYSIA: JOHOR: Gunung Ledang Recreational Forest (02.34°N, 102.63°E). La Sierra University Herpetological Collection LSUHC 8968. 07 June 2008. Juvenile, SVL 46 mm. Chan K. O., P. L. Wood Jr., and J. L. Grismer. Verified by L. L. Grismer. Currently known from N America, north to Nova Scotia, New Brunswick, S Quebec, and S Ontario (Canada), west to the central plains and south to Veracruz (Mexico); introduced on Cuba, Isla de Juventud (= Isla de Pinos), Puerto Rico, Hispaniola, and Jamaica in the Antilles; Europe, in Netherlands, Bordeaux region of France, Belgium, northern Italy, western Spain; Asia, in Java, Bali, Japan, northern Thailand, Korea, and Taiwan (Lever 2003. Naturalized Reptiles and Amphibians of the World. Oxford University Press, Oxford. 318 pp.). Specimen collected 2010 h from muddy drain by main trail. Another observed on the same night on rock besides main stream. The two juveniles in a natural habitat are suggestive of a local breeding population, and a cause for concern as this invasive species presents a danger to native anurans. Gunung Ledang is situated at least 8 km from the nearest town and is surrounded by oil palm and rubber estates. Because of its isolated location, specimens found are considered naturalized and not escapees from pet or food industry. First report in the wild from Peninsular Malaysia.

Submitted by **CHAN KIN ONN,** Institute for Environment and Development (LESTARI), Universiti Kebangsaan Malaysia, 43600 Bangi, Selangor Darul Ehsan, Malaysia (e-mail: kin_onn@yahoo.com); **PERRY L. LITHOBATES CATESBEIANUS (American Bullfrog). MÉXICO: HIDALGO: Municipality of Mineral el Chico, Ejido La Estanzuela (20.1088°N, 98.45255°W, WGS 84), 2734 m elev. 03 November 2007. Christopher Duifhuis Rivera. Verified by Luis Canseco Márquez. Colección Herpetológica del Museo de Zoología Alfonso L. Herrera, UNAM (MZFC-21372). First precise locality for Hidalgo, extending the known range ca. 80.23 km SW from the nearest known records in the Sierra Norte de Puebla (Smith and Smith 1976. Synopsis of the Herpetofauna of Mexico: Source Analysis and Index for Mexican Amphibians, IV. J. Johnson, North Bennington, Vermont. 1–9, A-A 1-G 12 pp.). The species was reported from Hidalgo by Canseco-Marquez et al. (2004. *In* Luna et al. [eds], Biodiversidad de la Sierra Madre Oriental, pp. 417–437. Las Prensas de Ciencias, México, D.F.), but with no specific locality. The specimen was found around the marshy edge of La Estanzuela's municipal water source located in pine forest.

OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). USA: FLORIDA: Clay Co.: Orange Park, 2884 Golden Pond Boulevard (30.18358°N, 81.78956°W; WGS84). 15 March 2008. Kenneth Beyerly. Florida Museum of Natural History, University of Florida (UF 152919). Adult female. New county record. In their map of Cuban Treefrog distribution in Florida, Meshaka et al. (2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida. 155 pp.) show a record from Clay Co. and cite Meshaka (1996. Herpetol. Rev. 27:37–40), who does not mention this county. A search of museum databases failed to find any specimens from this county. Franklin Co.: Carrabelle, 312 East Meridian Avenue (29.8518ºN, 81.661ºW). 5 July 2006. Rod Fasche. UF 151399. New county record and only the third voucher from the panhandle (Johnson 2004. Herpetol. Rev. 35:405; Krysko et al. 2005. Herpetol. Rev. 36:85–87). Lake Co.: Fruitland, U.S. Highway 441, 1.6 km S of Lake Griffin State Park (28.8440ºN, 81.8975ºW). 28 June 2005. John W. Strawbridge. UF 152458. New county record. Pasco Co.: New Port Richey, 5824 Baker Road (28.2440ºN, 82.6995ºW). 14 October 2002. David DeWitt. UF 134614–15. New county record. Putnam Co.: Hastings, County Road 13, 0.6 km S of State Road 207 (29.7085ºN, 81.5082ºW). 11 April 2006. John R. Rossi. UF 146299–300. Found in leaf of palm tree. New county record. Sumter Co.: Lake Panasoffkee, 2095 County Road 416N (28.7862ºN, 82.1454ºW). 28 May 2008. Nancy Dwyer. UF 152955–56. Found on house. New county record. Identification of all UF specimens was verified by Max A. Nickerson. *Osteopilus septentrionalis* has now been documented from 40 of 51 counties in peninsular Florida. It has not been reported yet from Baker, Bradford, Dixie, Gilchrist, Hamilton, Lafayette, Madison, Nassau, Suwannee, Taylor, and Union counties, all of which are located in the northern peninsula and have relatively low human population densities. Human-mediated dispersal of this species has been rapid and discontinuous via transport on cultivated palm trees, ornamental plants, vehicles, and trailers (Meshaka 1996, *op. cit.*). According to Meshaka (1996, *op. cit.*), *O. septentrionalis* was recorded from most counties in the southern two-thirds of the peninsula; since then, it has been recorded from 13 counties in the northern one-third of the peninsula and three of 16 counties in the panhandle. Reproducing populations are known to be present in Alachua, Levy, and Duval counties in the northern peninsula.

CROCODILIA – CROCODILIANS

CAIMAN CROCODILUS (Common Caiman). BRAZIL: CEARÁ: Crateús Municipality: District of Ibiapaba, Poty River (5.048579°S, 40.912588°W; WGS84). 24 April 2003. D. M. Borges-Nojosa. Collection of Herpetology of Núcleo Regional de Ofiologia (NUROF) - Universidade Federal do Ceará, Fortaleza, Brazil (CHUFC C044, adult, skin and bones). Verified by L. M. Verdade. Other specimen was observed walking on the road (5.116674°S, 40.804554°W; WGS84) between the local lagoons, showing the same habit registered by Olmos and Souza 1991 (Herpetol. Rev. 22:28–29). The species was previously known from Colombia, Peru, Bolivia, and in the Brazilian states of Amazonas, Pará, Maranhão, Mato Grosso, and Piaui (at Serra da Capivara National Park and basin river Parnaíba) (Carvalho 1951. Arquivos do Museu Nacional, XLII:127–152; King and Burke 1989. Crocodilian, Tuatara, and Turtle Species of the World. Association of Systematics Collections, Washington. 216 pp.). First state record; extends known distribution ca. 400 km airline NE of previously known range within Serra da Capivara National Park

(Arruda 1997. Conservação, Ecologia Humana e Sustentabilidade na Caatinga: Estudo da Região do Parque Nacional da Serra da Capivara - PI. IBAMA, Brasília. 96 pp.), and ca. 440 km airline from Lagoa do Muqueri (8.406687°S, 42.369043°W; WGS84), and Fazenda Veneza (8.751346°S, 42.265451°W; WGS84) (Olmos and Souza, *op. cit.*).

TESTUDINES – TURTLES

CARETTA CARETTA (Loggerhead Sea Turtle). TRISTAN DA CUNHA: near Edinburgh (37.04°S, 12.18°W), 6 May 2008. Verified by Bruce L. Wing, Curator, Reference Collections, NMFS Auke Bay Marine Station, Juneau, Alaska. Photographs and correspondence archived (AB 2008-0025) in herpetological collections of NMFS Auke Bay Marine Station. Edinburgh is on the north shore of Tristan da Cunha, ca. 4000 km E of South America, 2700 km W of South Africa, and 1100 ± km N of Antarctic Convergence. Juvenile female washed ashore on rocky coastline during a storm, tangled in discarded fishing net. Turtle had minor injuries as a result of struggle with netting and rocks, but was alert, vigorous, and apparently healthy. Released in waters off a sandy beach. First record from Tristan da Cunha.

Submitted by **ROBERT PARKER HODGE**, ME2, POB 1521, Gig Harbor, Washington 98335, USA; and **ERIK MACKENZIE**, Edinburgh, Tristan da Cunha.

DERMOCHELYS CORIACEA (Leatherback Sea Turtle). TRISTAN DA CUNHA: Nightingale Island (37.24°S, 12.29°W), March 1979. Verified by Denise Hamerton, Natural History Collection Manager, Iziko Museum: SA Museum. Nightingale Island is 38 km SSW of Tristan da Cunha, which is ca. 4000 km E of South America, 2700 km W of South Africa, and 1100 ± km N of Antarctic Convergence. Adult male, accessioned as SAM ZR 44953 on 24 February 1982 at Iziko Museum: South Africa Museum, Cape Town. First record from Tristan da Cunha.

Submitted by **ROBERT PARKER HODGE**, ME2, POB 1521, Gig Harbor, Washington 98335, USA; and **ERIK MACKENZIE**, Edinburgh, Tristan da Cunha.

GOPHERUS BERLANDIERI (Texas Tortoise). USA: TEXAS: ARANSAS CO.: Aransas National Wildlife Refuge (28.309478ºN, 96.803242ºW). 20 November 2007. Russell Jackson. Voucher images were taken by Darrin Welchert. Verified by Jonathan Campbell. Amphibian and Reptile Diversity Research Center UTADC 1974–1980. New county record (Dixon 2000. Amphibians and Reptiles of Texas, 2nd Edition. Texas A&M Univ. Press, College Station, Texas. 421 pp.). The captured adult male presented a heavy keratinous fungal infection on the marginal and costal scutes of the carapace, and the entire plastron. The specimen was marked and released in the Aransas National Wildlife Refuge.

Submitted by **AKIKO FUJII**, Department of Biology, Texas State University, San Marcos, Texas 78666, USA (e-mail: af@txstate.edu); **DARRIN WELCHERT**, Aransas National Wildlife Refuge, Victoria, Texas 77904, USA (e-mail: darrin_welchert@fws.gov); and **MICHAEL R. J. FORSTNER**, Department of Biology, Texas State University, San Marcos, Texas 78666, USA (e-mail: mf@txstate.edu).

GRAPTEMYS PSEUDOGEOGRAPHICA KOHNII (Mississippi Map Turtle). USA: TEXAS: MILAM CO.: Hatchling captured in the Little River (30.84188°N, 96.71916°W; NAD 83). 11 July 2008. James R. Dixon. Verified by Toby Hibbitts. Trapping conducted for the Texas Parks and Wildlife Department freshwater turtle assessment (Permit No. SPR-0102-191). Specimen deposited in the Texas Cooperative Wildlife Collection (TCWC 93025) at Texas A&M University College Station. New county record (Dixon 2000. Amphibians and Reptiles of Texas. 2nd Edition. Texas A&M Univ. Press, College Station. 421 pp.).

Submitted by **DONALD J. BROWN** and **MICHAEL R.J. FORSTNER**, Department of Biology, Texas State University – San Marcos, San Marcos, Texas 78666, USA; and **JAMES R. DIXON**, Department of Wildlife and Fisheries Sciences, Texas A&M University, College Station, Texas 77843, USA.

MACROCHELYS TEMMINCKII (Alligator Snapping Turtle). USA: TENNESSEE: HAMILTON CO.: Collegedale, Spalding Road, Wolftever Creek (35.0316°N, 85.0313°W). 03 June 2003. David B. Ekkens. Verified by A. Floyd Scott. Austin Peay State University photo archive, APSU 17486. New county record. Female turtle, exhibiting 8 annuli. Turtle trapped in a downstream-facing 0.94-m hoop trap baited with sardines. Paul Moler, Florida Fish & Wildlife Conservation Commission, performed analysis of the mitochondrial DNA from a tail-clipped tissue sample. The results showed that the turtle belonged to Haplotype A, commonly found in the Tennessee River system. Therefore, it is not clear if this animal is a natural occurrence or one that has been translocated, given that the nearest record on the Tennessee River is 550 river km from the present location.

Submitted by **DAVID B. EKKENS**, Biology Department, Southern Adventist University, Collegedale, Tennessee 37315, USA (e-mail: dekkens@southern.edu); and **DAVID COLLINS**, Curator of Forests, Tennessee Aquarium, Chattanooga, Tennessee 37401, USA (e-mail: dec@tennis.org).

PSEUDEMYS NELSONI (Florida Red-bellied Cooter). USA: FLORIDA: BRADFORD CO.: Starke, SR 16, 1.6 km W Clay County line (29.95483°N, 82.06454°W). 13 March 2008. J. M. Butler. Verified by M. A. Nickerson. UF 152531. Sub-adult male found DOR. A second specimen UF 153667 was found DOR on 30 August 2008. New county record (Jackson 2006. *In* P. A. Meylan [ed.], Biology and Conservation of Florida Turtles, pp. 313–324. Chelonian Research Monographs No. 3.

Submitted by **BENJAMIN K. ATKINSON** (e-mail: bka@ufl.edu) and **J. MICHAEL BUTLER**, Department of Herpetology, Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611, USA.

TERRAPENE ORNATA (Ornate Box Turtle). USA: ILLINOIS: SCOTT CO.: 7.4 km WSW of Winchester, and 8.9 km WNW of Alsey, crossing 700E (Hillview Road), 0.08 km S of jct with 500N (Lashmett Road) (39.59365ºN, 90.52889ºW). 01 June 2008. Veri-

fied by Chris Phillips, Illinois Natural History Survey. Photographic voucher INHS 2008.13. New county record (Phillips 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Natural History Survey Manual 8:xv, 1–282). Adult female collected by John K. Tucker. Turtle was returned alive to collecting locality after tissue sample was obtained.

Submitted by **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA; **CHAD R. DOLAN,** Iowa Department of Natural Resources, Lake Darling Station, 110 Lake Darling Road, Brighton, Iowa 52540, USA; and **JAMES T. LAMER,** Western Illinois University, 1 University Circle, Macomb, Illinois 61455, USA.

TRACHEMYS SCRIPTA TROOSTII (Cumberland Slider). USA: NORTH CAROLINA: Madison Co.: 7.1 km NW Hot Springs, French Broad River near Huff Island (35.933477°N, 82.886194°W, WGS84). 07–08 August 2008. Jeffrey C. Beane, Robert A. Davis, and L. Todd Pusser. Two juveniles taken in hoop-style turtle trap baited with sardines. Verified by William M. Palmer. North Carolina State Museum of Natural Sciences (NCSM 74447–74448). A third subadult was observed basking in the French Broad River at 4.8 km NW Hot Springs (35.924467°N, 82.86235°W, WGS84) on 08 August 2008. New county records and first confirmed records for North Carolina (Palmer and Braswell 1995. Reptiles of North Carolina. University of North Carolina Press, Chapel Hill. 412 pp.). Extends range ca. 50 km SE of nearest records in Tennessee (Iverson 1992. A Revised Checklist with Distribution Maps of Turtles of the World. Privately published, Richmond, Indiana. xiii + 363 pp.).

Submitted by **JEFFREY C. SQUAMATA – LIZARDS

AGAMA AGAMA AFRICANA *(*African Rainbow Lizard*)*. USA: FLORIDA: Hillsborough Co.: Apollo Beach: NE corner U.S. 41 and county road 672 (27.793155°N, 82.383603°W; WGS84). 26 December 2007. J. Steve Godley. Verified by Kenneth L. Krysko, Florida Museum of Natural History (FLMNH), Gainesville, Florida (UF 152540, color photo; USNM 565101, specimen). New county record (Enge et al. 2004; Florida Sci. 67:303–310). Population of 12–15 individuals first detected at 7-11 store on road corner noted above. On this same day one adult female and three juveniles observed at an abandoned building 180 m to the N and ca. 30 observed 365 m to the NE at the 2.0-ha compound of Segrest Farms #1 (complete search not possible), all within NE quadrant of road intersection. A follow-up survey on 06 June 2008 showed similar numbers of active agamas at the 7-11 store and Segrest; the abandoned building had been removed with none observed. Three adult males, two females, and two juveniles also seen from outside the south fence of a Cemex Ready-Mix plant 200 m E of Segrest. Searches of other likely edificarian sites within 1.6 km of this intersection failed to detect the species on either day. Both sexes and multiple size classes observed at 7-11 store, Segrest Farms, and Cemex plant suggests an established, breeding population that may total 100 adults. The owner of Segrest Farms (Jack Brandon, pers. comm.), an exotic fish and reptile dealer, acknowledged they had sold *A. a. agama* up to 3–4 years ago, and despite multiple security fences "some may have escaped." Additional Hillsborough County populations are catalogued in the Florida Museum of Natural History (FLMNH UF 152788 and 153456–153457, photo vouchers; UF 153458, specimen)..

ANOLIS CAROLINENSIS (Green Anole). USA: TEXAS: DeWitt Co.: State Highway 183 in the town of Cuero (29.09114°N, 97.29095°W; WGS84). 28 June 2008. Romey Swanson, Vincent Farallo, Jeff Troy, and Glen Hood. Verified by James R. Dixon, Texas Cooperative Wildlife Collection (TCWC 93071). A single adult was found and captured by hand on the sidewalk of the town square. This individual represents the first recorded occurrence of this species in DeWitt County (Dixon 2000. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Publ. Texas A&M University Press. 421 pp.).

Submited by **ROMEY L. SWANSON** , **VINCENT R. FARALLO**, **JEFF R. TROY**, **GLEN R. HOOD**, and **MICHAEL R. J. FORSTNER**, Department of Biology, Texas State University, San Marcos Texas 78666, USA (e-mail: rs56761@txstate.edu).

BASILISCUS VITTATUS (Brown Basilisk). USA: FLORIDA: Hendry Co.: Clewiston, 0.5 km SE of Evercane Road on Old U.S. Highway 27 (26.7449°N, 80.8979°W; WGS84). 17 May 2008. Tom Crutchfield. Florida Museum of Natural History, University of Florida (UF 152897). Juvenile collected along canal on S side of road; all age classes observed. Verified by Kenneth L. Krysko. New county record and extends range 59 km W of nearest known population in Palm Beach Co. (Krysko et al. 2005. Herpetol. Rev. 36:85–87).

Submitted by **TOM E. CRUTCHFIELD**, 4681 SW 33rd Avenue, Fort Lauderdale, Florida 33312, USA (e-mail: tomcrutchfield@hotmail.com); and **KEVIN M. ENGE**, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA (e-mail: kevin.enge@myfwc.com).

HEMIDACTYLUS FRENATUS (Common House Gecko). VANUATU: MALEKULA: Nabelchel Bungalows, Norsup (16.073679ºS, 167.398024ºE). Philip de Pous. Verified by Wouter Beukema. Specimen (http://calphotos.berkeley.edu, digital image voucher 0000 0000 0908 0035) found on wall of dining room on 29 July 2007. Besides Efate and Esperitu Santo (Case et al. 1991. Evol. Ecol. 5:272–290), Malekula is the third island invaded in Vanuatu Archipelago.

Submitted by **PHILIP E. DE POUS**, Department of Animal Management, University of Applied Sciences Van Hall Larenstein, 8934 CJ Leeuwarden; e-mail: phillip.depous@wur.nl.

LEIOCEPHALUS CARINATUS (Northern Curly-tailed Lizard). USA: FLORIDA: Alachua Co.: Gainesville, University of Florida campus, McCarty Hall (29.646487ºN, 82.34582ºW, Datum WGS84). 25 September 2008. Kenneth L. Krysko, Michael C. Granatosky, and Tina M. Bouse. UF 153707. Verified by Steve A. Johnson. New county record, and extends known range of this species ca. 177.5 km SW of closest known record in Jacksonville, Duval County (Krysko and Burgess 2008. Herpetol. Rev. 39:368). Collected on limestone boulder.

Submitted by **KENNETH L. KRYSKO** (e-mail: kenneyk@flmnh.ufl.edu) and **MICHAEL C. MABUYA ALTAMAZONICA (NCN). COLOMBIA: META: "Finca Santa Teresita 15 km NE Villavicencio" (04.1533°N, 73.635°W; WSG 84, Fallingrain Gazetteer) University of Texas at Arlington (UTA R-3304), 14 June 1969, W. F. Pyburn; "Near Caño Blanco, ca. 15 km WSW Vista Hermosa" (03.0864°N, 73.7514°W,WSG 84, Fallingrain Gazetteer), (UTA R-3358), J. R. Glidewell, 10 March 1971; Lomalinda (not traced; UTA R-3546 and R-5027), respectively 16 September, 1971 by J. K. Salser, Jr., and 21 June 1974 by W. F. Pyburn. VAUPÉS: Timbó (approximately 01.10°N, 69.92°W, elev. 168 m, fide Campbell and Clarke 1998. Herpetologica 54:301–317; UTA R-3586), J. K. Salser, Jr., 25 June 1972; Wacará (this locality is located east of Mitú near the Brazilian border at approximately 1.15°N, 69.92°W, elev. 213 m, fide Campbell and Clarke 1998, *op. cit.*; UTA R-3944–46), J. K. Salser, Jr., 4–19 September 1973. ECUADOR: PASTAZA: "Río Cononaco." This specimen was found about 4 m above ground in the thatched roof hut in primary rainforest in a small village of Auca Indians (1–2°S, 76.5–75.5°W), M. B. Harvey, June, 1984. Verified by E. N. Smith.

These records are the first reports of *Mabuya altamazonica* from Colombia and Ecuador. Reported from Peru in the original description (Miralles et al. 2006. Zootaxa 1188:1–22), this species extends south in rainforests along the Andes to Buenavista, Santa Cruz, Bolivia (Harvey et al. 2008. Zootaxa 1828:43–56).

Submitted by **MICHAEL B. HARVEY**, Department of Biology, Broward College, 3501 S.W. Davie Road, Davie, Florida 33314, USA; e-mail: mharvey@broward.edu.

PHELSUMA MADAGASCARIENESIS GRANDIS (Madagascar Day Gecko). USA: FLORIDA: Monroe Co.: Key West, 1225 South Street (24.552797ºN, 81.787325ºW, WGS84; elev. < 1 m). 7 May 2008. Phyllis Rose. Verified by Kevin M. Enge. Florida Museum of Natural History (photographic voucher UF 152814). New island and most southern record in the United States (Krysko and Hooper 2007. Gekko 5:33–38). Palm Beach Co.: Lake Worth, 820 North O Street (26.625634ºN, 80.05083ºW, WGS84; elev. < 1 m). 30 August 2008. Carl D. May. Verified by Kevin M. Enge. Florida Museum of Natural History (photographic voucher UF 153515). New county record and extends the range ca. 190 km N of the closest known locality on Plantation Key, Monroe County (Krysko and Hooper 2007, *op. cit.*).

Submitted by **KENNETH L. KRYSKO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu); **ANDREW P. PLESTIODON (=EUMECES) EGREGIUS (Mole Skink). USA. FLORIDA. Walton Co.: Nokuse Plantation, 3.5 km NE of Bruce and 57 m E of SR 81 (30.495867ºN, 85.930457ºW). 14 April 2008. Matthew J. Aresco. Verified by Jason Butler, Florida Museum of Natural History, Gainesville, Florida (UF 153017). New county record (Ashton and Ashton 1991. Handbook of Reptiles and Amphibians of Florida. Part II. Lizards, Turtles & Crocodilians. Second Edition. Windward Publishing, Miami, Florida. 191 pp.). Adult found dead on surface following prescribed burn.

Submitted by **MATTHEW J. ARESCO**, **FRANK N. CUCHENS**, **SANTIAGO H. CRUZ**, and **ROBERT N. WALKER**, Nokuse Plantation, 13292 Co. Hwy 3280, Bruce, Florida 32455, USA (e-mail: aresco@nokuse.org).

SCELOPORUS SUGILLATUS (Variable Yarrow's Spiny Lizard). MÉXICO: DISTRITO FEDERAL: Delegación Magdalena Contreras, Cuarto Dínamo, área de Coconetla (19.259°N, 99.302°W, WGS 84), 3385 m elev. 19 January 2006. Uri Omar García Vázquez. Verified by Edmundo Pérez Ramos. Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México (MZFC 19893). First record for Distrito Federal, extending the

known range ca. 23 km N from Parque Nacional Lagunas de Zempoala, Huitzilac, Morelos (Smith 1942. Proc. U.S. Nat. Mus. 92:349–395). The specimen was under a rock in fir forest. Field work funded by "Manejo de Ecosistemas y Desarrollo Humano" UNAM (SDEI-PTID-02).

Submitted by **ANDRÉS ALBERTO MENDOZA-HERNÁNDEZ** (e-mail: andalmeher@ yahoo.com), **URI OMAR GARCÍA-VÁZQUEZ** (e-mail: urigarcia@hotmail.com), and **ADRIÁN NIETO-MONTES DE OCA,** Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, Apartado Postal 70-399, México, Distrito Federal 04510, México.

SQUAMATA – SNAKES

AGKISTRODON CONTORTRIX CONTORTRIX (Southern Copperhead). USA: ARKANSAS: Searcy Co.: ca. 0.5 km E of jct AR 14 and Searcy Co. Rd. 61 (36.0153°N, 92.3231°W; NAD 83). 11 August 2008. M. B. Connior. Verified by S. E. Trauth. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31240). Adult found DOR on Searcy Co. Rd. 61. First county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univeristy of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **MATTHEW B. CONNIOR,** Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA; e-mail: matthew.connior@smail.astate.edu.

CLONOPHIS KIRTLANDII (Kirtland's Snake) USA: INDIANA: Hendricks Co.: 39.67542ºN, 86. 34102ºW. 02 August 2004. B. Jagger Foster and the Indianapolis Airport Authority Bat Crew. ISUVC 3893. Verified by Dale W. Sparks. New county record (Minton 2001. Amphibians and Reptiles of Indiana. Second Ed. Indiana Acad. Sci. 404 pp.)

Submitted **by B. JAGGER FOSTER**, Indiana State University, Biology Department, 600 North 6th St. Terre Haute, Indiana 47809-1905, USA.

COLUBER CONSTRICTOR FLAVIVENTRIS (Eastern Yellow-bellied Racer). USA: TEXAS: McMullen Co.: Hwy 72, 6 km E of jct with Hwy 16 (28.46025°N, 098.49085°W; WGS 84). 28 June 2008. Vincent Farallo, Romey Swanson, Jeff Troy, and Glen Hood. Verified by James R. Dixon, Texas Cooperative Wildlife Collection (TCWC 93076). The snake was found crossing the road at ca. 0100 h and represents the first recorded specimen for McMullen County (Dixon 2000. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **VINCENT R. FARALLO (**e-mail: VF1030@txstate.edu), **ROMEY L. SWANSON**, **JEFF R. TROY**, **GLEN R. HOOD**, and **MICHAEL R.J. FORSTNER**, Department of Biology, Texas State University, San Marcos, Texas 78666, USA.

COLUBER CONSTRICTOR LATRUNCULUS (Black-masked Racer). USA: TENNESSEE: Fayette Co.: Wolf River Wildlife Management Area, Yager Drive just south of Yager Bridge (35.0313889°N, 89.2469444°W). May 2007. Eric P. Johansen and Joshua T. Ream. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 18934). Adult found dead on road. New county record (Thomas et al. 2000. Herpetol. Rev. 31:54).

Submitted by **ERIC PAUL JOHANSEN (**e-mail: ejohansen14@apsu.edu) and **JOSHUA TAYLOR REAM**, Department of Biology and Center of Excellence for Field Biology, Austin Peay State University, Clarksville, Tennessee 37044, USA.

CONOPSIS ACUTA (NCN). MÉXICO: GUERRERO: Municipality of Malinaltepec: Ejido Tres Marías (17.07357°N, 98.41424°W, WGS 84), 2331 m elev. 29 June 2006. Uri García Vázquez and Itzel Durán Fuentes. Verified by Luis Canseco Márquez. Museo de Zoología, Facultad de Ciencias, UNAM (MZFC 20906). First record for Guerrero, extending its known range ca. 83.21 km (airline) E from the closest locality, 3 mi SE of Tlaxiaco, Oaxaca (Goyenechea and Flores-Villela 2006. Zootaxa 1271:1–27). The snake was found under a rock in pine-oak forest.

Submitted by **URI OMAR GARCÍA-VÁZQUEZ (**e-mail: urigarcia@gmail.com), **EDMUNDO PÉREZ-RAMOS,** and **ITZEL DURÁN-FUENTES,** Museo de Zoología, Facultad de Ciencias, UNAM, A.P. 70-399, México D.F. 04510, México.

CROTALUS HORRIDUS (Timber Rattlesnake). USA: TEXAS: Montague Co.: Hwy 677 (33.845ºN, 97.489ºW), large adult male DOR. 21 May 2008. Jesse M. Meik and Felipe Avila. Verified by Carl Franklin. University of Texas at Arlington Collection of Vertebrates (UTA R-55989). First county record (Werler and Dixon 2001. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, xv + 437 pp.). *Crotalus horridus* has a fragmented distribution throughout the eastern third of Texas; UTA R-55989 represents the northwestern-most locality for the state. Habitat at the time of collection consisted of a mosaic of rural/agricultural lands and Post Oak (*Quercus stellata*)/Blackjack Oak (*Q. marilandica*) woodlands.

Submitted by **JESSE M. MEIK (**e-mail: jmeik@uta.edu) and **FELIPE AVILA**, Department of Biology, The University of Texas at Arlington, Arlington, Texas 76019, USA.

CROTALUS TRANSVERSUS (Cross-banded Mountain Rattlesnake). MÉXICO: DISTRITO FEDERAL: Delegación Magdalena Contreras, Cerro Panza, Valle del Tezontle (19.13155°N, 99.1782°W; datum WGS 84). 3430 m elev. 20 May 2007. Uri Omar García Vázquez. Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México (MZFC 20521). Verified by Oscar Flores Villela. First record for Distrito Federal, extending the known range of the species ca. 21.4 km N from Parque Nacional Lagunas de Zempoala, Huitzilac, Morelos (Campbell and Lamar 2004. Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 870 pp.). The specimen was found crawling on a road in pine forest. Field work funded by Manejo de Ecosistemas y Desarrollo Humano, UNAM (SDEI-PTID-02).

Submitted by **URI OMAR GARCÍA-VÁZQUEZ** (e-mail: urigarcia@hotmail.com), **ISRAEL SOLANO-ZAVALETA**, and **ADRIÁN NIETO-MONTES DE OCA**, Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, A. P. 70-399, México, Distrito Federal 04510, México.

CROTALUS WILLARDI MERIDIONALIS (Southern Ridge-nosed Rattlesnake). MÉXICO: DURANGO: Municipality of Tepehuanes: 24 km SW Tepehuanes (25.1°N, 105.8°W; WGS84), 2600 m elev. 31 July 2007. Jason M. Jones. UTA Digital Collection (UTADC 1088). 28 km SSE Tepehuanes (25.1°N, 105.5°W, WGS84), 2600 m. elev. 1 August 2007. Chris I. Grünwald, Jacobo Reyes-Velasco and Ginny N. Weatherman. UTA Digital Collection (UTADC 1089). Both specimens verified by Robert W. Bryson, Jr. Northernmost records for *Crotalus willardi meridionalis* and extends known range ca. 150 km N from localities near El Salto, Durango (Armstrong and Murphy 1979. Univ. Kansas Publ. Mus. Nat. Hist. Spec. Publ. No. 5:1–88). The locality is also ca. 300 km SE from the southernmost locality for *C. willardi silus*, located between Urique and Cerocouhui, Chihuahua (Tanner 1985. Great Basin Nat. 45:615–676).

Submitted by **JACOBO REYES-VELASCO**, Centro Universitario de Ciencias Biológicas y Agropecuarias, Carretera a Nogales Km. 15.5, Las Agujas, Nextipac, Zapopan, Jalisco, México (e-mail: jackobz@gmail.com); **CHRISTOPH I. HELICOPS ANGULATUS (Water's snake). BRAZIL: CEARÁ: Aquiraz Municipality: Batoque Lagoon. (03.995253°S, 38.241394°W; WGS84). 11 June 2008. V. Lima-Verde, P. C. M. D. Mesquita, and H. Fernandes-Ferreira. Collection of Herpetology of Núcleo Regional de Ofiologia (NUROF) - Universidade Federal do Ceará, Fortaleza, Brazil (CHUFC 2961). Verified by C. Strüssmann. The species was previously known from Amazon Forest (Ecuador, Venezuela, Colombia, Bolivia, Peru, French Guiana, Trinidad, and Brazil (states of Acre, Amazonas, Maranhão, Pará, and Rondonia) (Cunha and Nascimento 1978. Publicações Avulsas do Museu Paraense Emílio Goeldi 31:1–218; Jorge-da-Silva 1993. Herpetol. Nat. Hist. 1:37–86; Frota 2005. Phyllomedusa 4[1]:61–67), Pantanal (State of Mato Grosso) (Marques et al. 2005. Serpentes do Pantanal. Holos, Ribeirão Preto. 184 pp.), and Atlantic Forest (State of Paraíba) (Santana et al. 2008. Biotemas 21[1]:75–84). First state record; extends known distribution ca. 510 km airline E of previously known range within Nova Vila (Maranhão; 03.768042°S, 45.164173°W, WGS84), and 770 km airline NW from João Pessoa (Paraíba; 07.136732°S, 34.860413°W, WGS84). This specimen and a *H. leopardinus* were found in a lacustrine environment (freshwater marshes and dunes). This is the first record for this species from the coastal environment.

Submited by **DIVA MARIA BORGES-NOJOSA** (e-mail: dmbnojosa@yahoo.com.br), **PAULO CESAR MATTOS DOURADO DE MESQUITA** (e-mail: paulocmdm@gmail.com), and **HUGO FERNANDES-FERREIRA,** Universidade Federal do Ceará, NUROF-UFC, Campus do Pici, Bloco 905, 60455-760, Fortaleza, Ceará, Brazil (e-mail: hugofernandesbio@gmail.com).

LAMPROPELTIS CALLIGASTER RHOMBOMACULATA (Mole Kingsnake). USA: ALABAMA: Chilton Co.: 9.0 km S of CR 25 on CR 73 (33.00685°N, 86.52074°W; WGS84). 25 May 2000. J. Burling. Verified by Joseph R. Mendelson III. University of Montevallo Collection of Vertebrates (UMCV-RS0083). Female containing five eggs found dead on road. New county record; fills a gap among Shelby, Bibb, and Coosa counties (Mount 1975. The Reptiles and Amphibians of Alabama. Univ. Alabama Press, Tuscaloosa. 347 pp.). Alabama Department of Conservation and Natural Resources collecting permit number 1044 (JWB).

Submitted by **JOHN W. BURLING[1]** and **JILL A. WICKNICK[2]**, Departments of Psychology[1] and Biology[2], University of Montevallo, Montevallo, Alabama 35115, USA; e-mail: wicknickja@montevallo.edu.

LETHEOBIA CROSSI (Crosse's Blind Snake). TOGO: CENTRAL REGION: Fazao (08.42°N, 00.48°E). Between June and December 2007. Collector unrecorded. Institut de Recherche pour le Développement at Dakar (IRD 92-T). Verified by Youssouph Mané. First record for Togo. Extension of range by ca. 600 km W from closest known locality at Wushishi in Nigeria (Butler and Reid 1990. Nigerian Fld. 55:19–40). The genus *Letheobia* was recently revived (Broadley and Wallach 2007. Zootaxa 1515:31–68). Species also obtained from a farmer at Alédjo Kadara (09.15°N, 01.13°E) (IRD 102–T). Before these records, *L. crossi* was known from Nigeria, including Asaba (type locality: 06.11°N, 06.45°E), Agweri (06.20°N, 06.53°E), Wushishi (09.44°N, 06.04°E), and Calabar (04.48°N, 08.21°E) (Butler and Reid 1990. Nigerian Fld. 55:19–40; Roux-Estève 1974. Mém. Mus. Nat. Hist. Nat., Ser. A, 87:1–313).

PYTHON RETICULATUS (Reticulated Python). PHILIPPINES: BATANES PROVINCE: Itbayat Island (20.75ºN, 121.8333333ºE). 10 February 2001. Specimen released alive. Photograph verified by M. Auliya (MCZ R-186014). A widespread and commonly encountered species, being found throughout mainland Southeast Asia and the Indo-Malay-Philippine archipelago but the true limits of its range are more difficult to determine because most authors are satisfied to list countries rather than exact localities. The southeastern limits of the range are the islands to the west of New Guinea, i.e., Seram and Tanimbar Islands (Rooji 1917. The Reptiles of the Indo-Australian Archipelago. Vol. II. Ophidia. E. J. Brill, Leiden. xiv + 334 pp; Kopstein 1927. Zool. Meded. [Leiden] 9:71–112; de Haas 1950. Truebia 20:511–625). The northern limits of the range are more difficult to determine. This species is not believed to occur in China even though de Haas (*op. cit.*) records "S. China?", Zhao and Adler (1993. Herpetology of China. Society for the Study of Amphibians and Reptiles, Oxford, Ohio. 522 pp. + 48 pl. + 1 folding map) omitted the species, and Pope (1935. The Reptiles of China. Natural History of Central Asia. Vol. 10. American Museum of Natural History, New York. li + 604 pp.; 27 pl.) stated that despite earlier reports, it is unlikely that *P. reticulatus* is part of the Chinese herpetofauna, further suggesting that occasional specimens might have been deliberately transported into the country by travelers. Neither has *P. reticulatus* been recorded from Taiwan (Kuntz 1963. Snakes of Taiwan. US Naval Research Unit No. 2:1–80). de Haas (*op. cit.*) recorded *P. reticulatus* from "Burma; Siam as far north as lat. 18°; Indochine." Taylor (1965. Univ. Kansas Sci. Bull. 45[9]:609–1096) stated that the species is found throughout Thailand "except perhaps the northern parts." Smith (1943. Fauna of British India: Reptilia and Amphibia. Vol. III. Serpentes. Taylor and Francis, London. xii + 583 pp. + 1 map) listed "Tenasserim" in southern Burma (Myanmar), Siam (Thailand) as far north as lat. 18°, and French Indo-China (Vietnam) as far north as "Yen-Bai in Tong-King." Yen-Bai is both a province and provincial capital located at 21°45'N, 104°50'E. Khan (1982. Wildlife of Bangladesh: A Checklist. Univ. Dhaka, Dhaka. 173 pp.) records *P. reticulatus* from Sylhet Division, between 24°00' and 25°10'N and includes a plate of an identifiable processed skin, this being the northernmost record for Bangladesh, the earlier report from the Shishak River on the border with northeastern India (Mountfort 1969. The Vanishing Jungle: The Story of the WWF Expedition to East Pakistan. Houghton Mifflin, New York. 286 pp.), being a misidentified *P. molurus* (Funk 1979. Bull. Chicago Herpetol. Soc. 14[3]:92).

All the major islands of the Philippines fall within the known range of *P. reticulatus*. Alcala (1986. Guide to Philippine Flora and Fauna. Vol. X. Amphibians and Reptiles. Natural Resources Management Centre, Ministry of Natural Resources and University of the Philippines, Manila. xiv + 195 pp.) records it as "Found all over the Philippines."

In the process of filming a documentary in the Philippines, we visited Itbayat, the northernmost inhabited island in the Batanes Islands, 320 km N of Luzon and 200 km SE of Taiwan. The herpetofauna of Itbayat is low in diversity and we recorded only *Hemidactylus frenatus* (Common House Gecko) and *P. reticulatus*, the latter as two specimens. One was a 2.0–3.0 m captive specimen in Mayan town. It had been captured in a chicken coop and offered to us for sale. Ownership of the python was negotiated, without payment, before it was photographed extensively and released. A second specimen, killed near a goat paddock, was much larger. A large part of its skin was preserved as a tanned roll and some had been used on a local banjo. These two Itbayat specimens constitute the northeasternmost, possibly also the northernmost, records for *P. reticulatus*.

We thank YAP Films and Animal Planet for support of the project.

e-mail: burbrink@mail.csi.cuny.edu

It seems nearly impossible that a person could write a credible biography of someone they never met and accurately capture the subject's personality and the intimate details of their life. Jamie James has not only done this with his biography of Joe Slowinski in the new book, *The Snake Charmer: a Life and Death in the Pursuit of Knowledge*, but he has actually done it well and given us an entertaining read to boot. I anticipated the release of this book for sometime and am very pleased with the final product. I will admit that my review of this book is somewhat biased as Joe Slowinski was a very good friend of mine and I was interviewed extensively by James for this book. Nevertheless, I think it is not only an important document for the layperson interested in the process of science, snakes, and adventure, but also a fantastic contribution to the history of herpetology. Ultimately, James admits that he wrote this book to question what drives a person to spend their life investigating snake evolution at the expense of health, finances, relationships, and personal comfort. Obviously, for most readers of *Herpetological Review*, the answer to this question is obvious—it's what we do for fun and we can't help it. Jamie James traces the life of Joe Slowinski in order to get an even better understanding of how to frame such a question and I'll not spoil the book by giving my impression of that.

Beyond exploring this somewhat nebulous question, the real charm in *The Snake Charmer* is that it explores and documents the life of Joe Slowinski, with an emphasis on his academic development, life as a field researcher, personal relationships, and the social nature of herpetologists. For those who did not know Joe, I can honestly say that James' writing captures Joe's personality and passion for herpetology well. So, how is it that James, who never met Joe, was able to provide us with such a good characterization of Slowinski's personality and abilities as a scientist? James thoroughly examined all of Joe's personal journals and correspondence with friends and researchers—Joe was meticulous and kept most written interactions with everyone he encountered. Additionally, James conducted numerous (and very long) interviews with family, friends, and fellow researchers to provide even more detail on Joe's life to relay a real sense of his mannerisms and rough but loveable personality. The result is a pretty detailed journey through Joe's life that is seasoned with quotes and stories from his family, friends, and (importantly for our crowd) luminaries in herpetology and evolutionary biology.

For many people curious about this book, I am sure that a primary motivation for purchasing it is to read the gruesome events documenting Joe's final tragic collecting expedition near Rat Baw, Burma. Certainly much of Joe's life has been boiled down in the popular press to his final 36 hours and his struggle for life after being bitten by a krait (*Bungarus*). The last events of Slowinski's life are definitely covered here, in fact nearly a third of book describes every aspect of this grim event—including funding, preparation, hardships in the field, inefficiency of the Burmese government, tensions among the field crew, Joe's bite, resuscitation efforts, his death, handling the remains, and subsequent grief for all those who cared about him. Thankfully, *The Snake Charmer* covers much more of Slowinski's life and personal achievements.

The Snake Charmer is broken into 13 unnumbered chapters and one epilogue. Each chapter is named after a single snake species and is prefaced by an illustration and an accompanying discussion of various aspects of the biology of the particular serpent. Most of these snakes are in some way tied to particular events in Joe's life in said chapter. I thought this was a clever way to introduce different events or facets of Joe's life and, excluding *Oxyuranus microlepidotus*, I am certain Slowinski collected all of these snakes. The book also provides two sections of photos—the first are shots capturing Joe's childhood with friends and family (and some herps) and the second is composed mostly of pictures of Joe and colleagues in Burma. I wish a section of photographs had been included showing reptiles and amphibians that Joe would have encountered or worked on throughout his life (or at least the ones named in his honor).

The Snake Charmer opens with a discussion of venomous snake mimicry (emphasizing the model/mimicry system in *Dinodon* and *Bungarus*), krait venom, and Joe's fatal encounter with this snake. The following chapters detail Joe's life chronologically and do not return to the fatal encounter with the krait until the last section of the book, entitled 'The Expedition.' In between, James traces Joe's interest and academic development in general science, geology, and ultimately herpetology. Along with descriptions of his keen intellect, we are also given a fairly accurate depiction of the warmth, humor, generosity, debauchery, and rough and rowdy ways that characterized Slowinski's personality. Joe's early life in Manhattan, Tokyo, and Kansas City are thoroughly explored through interviews with his family and it clearly shows how an inherently curious kid, capturing a rat snake (*Pantherophis obsoletus*) at the age of five, was encouraged and aided by his mother to study natural history. Eventually, this would develop into a passion for snakes. As an undergraduate at the University of Kansas, we learn about Joe's passion for evolution, paleontology, and snakes. In these chapters covering Joe's early life, it is evident that he was completely fascinated with collecting snakes and venomous ones in particular—leading to two crotaline envenomations.

The book then turns to Joe's career as a doctoral student at the University of Miami, where he was mentored by Jay Savage, and his early contributions to herpetology and evolutionary biology. For herpetologists interested in the social aspects of our field, the book becomes particularly important for documenting the personality of other major players in the field. For me, a quote by Savage on page 73 about why scientists build phylogenies when we know they may be incorrect is classic and completely worth the price of this book. After completing his doctorate on the taxonomy of New World coral snakes, the book traces Joe's life through his postdoc years researching krait evolution at the National Museum of Natural History and Louisiana State University Museum of Natural Science, where he was again envenomated by another crotaline (*Sistrurus miliarius*). As the book correctly describes, these were tough days for Slowinski—he had great difficulty obtaining a professorial position at a university and was living on a very meager salary. Although these aspects of his life may seem somewhat dry, I can assure you they are not. These sections are laced with some pretty spicy and exciting stories that illustrate Joe's wild side, including some run-ins with the law.

The last portion of the book describes his curatorial position at the California Academy of Sciences, research in Burma and China, and his success at obtaining a massive NSF grant to fund expeditions in Burma. With funds for research, a new romance, and respect in the field, we learn how life was certainly looking up for Joe. And then the book turns to his last trip to Burma. James relates in excruciating detail Joe's final collecting trip to northern Burma and the hardships faced by him and his crew on this adventure. I think anyone reading this will find the end of the book difficult to stomach. The account of Joe's fatal bite, the impossibilities faced by his crew to sustain his life, and Slowinski's eventual passing is pretty rough stuff. Hopefully, this last episode will teach scientists working with venomous snakes to proceed with caution. 'The Expedition' section is appropriately followed by an epilogue that frames life at the California Academy after Joe's death and discusses the species named in his honor.

The Snake Charmer is a quick read, well written, and should be of great interest to readers of this journal. In fact, I doubt many books reviewed here contain as much drama, action, and adventure—peppered with a host of romantic and villainous characters (you can figure out who the villains are). Other than a few errors about Joe being the only academic herpetologist killed in the field from a venomous snake bite (although Schmidt and Mertens were envenomated in their labs, it could be argued that Fred Shannon was an academic herpetologist and certainly he died in the field from the bite of a *Crotalus scutulatus*), and some half-baked theories on why *Boa constrictor* does not lay eggs and a prediction of impending infertility for dwarf members of this same species in Cozumel, the text is thorough and well-researched. At a cover price of US $24.95, even the most frugal herpetologist should be able to afford it. This book sits on my shelf right next to other stalwart classics in the history of herpetology (or herpetological biographies): *Snakes and Snake Hunting* (Kauffeld 1957), *Snakes*: *the Keeper and the Kept* (Kauffeld 1969), *Edward H. Taylor: Recollections of a Herpetologist* (Taylor et al. 1975), *A Field Guide to the Life and Times of Roger Conant* (Conant 1997), and *Contributions to the History of Herpetology* (Adler 1989, 2007). As the artist Jack Kirby used to say "Don't ask, just buy it!"

This volume is a comprehensive review of research on snapping turtles. In the tradition of Gibbons' (1993) volume on slider turtles, Steyermark, Finkler, and Brooks have assembled an impressive roster of turtle biologists to write individual chapters relating to all aspects of snapping turtle biology. The book begins with an introduction by Whit Gibbons. The majority of the book is divided into three sections. The first, containing Chapters 1–4, covers taxonomy and systematics. The second section, containing Chapters 5–11, covers physiology, energetics, and growth. The third section, with Chapters 12–17, covers life history and ecology. The book concludes with a list of references and an index.

Chapter 1, by Carl Ernst, is a taxonomic overview of chelydrid turtles. Distribution, characteristics, geographic variation, and recorded fossils are provided for all extant chelydrid taxa including the alligator snapping turtle (*Macrochelys temminckii*) and the central and South American snapping turtles (*Chelydra rossignonii*

and *C. acutirostris*).

J. Howard Hutchison reviews fossil chelydrids in Chapter 2. Prior to reading this chapter I was unaware of the broad geographic distribution of fossil chelydrids and was surprised to learn of early Eocene snapping turtle fossils from Ellesmere Island in Canada! This chapter presents a phylogenetic analysis of fossil chelydrids although it could be easily overlooked as there is no discussion of the methods used and the resulting phylogenetic tree is only about 3 cm wide, part of an eight-panel, quarter page figure.

Chapter 3, by Eugene Gaffney, provides an overview of the snapping turtle skull and a summary of the literature pertaining to snapping turtle morphology. A large amount of descriptive and comparative work has been published concerning snapping turtle morphology in the past and Gaffney does an outstanding job summarizing that literature. The chapter is illustrated with several line drawings of snapping turtle skulls. There are, however, some missing citations pertinent to snapping turtle skeletal morphology such as Zangerl (1939) and recent papers by Sheil and Greenbaum (2005) and Jamniczky and Russell (2007). These omissions though do not detract from the thoroughness and usefulness of this chapter.

Shaffer, Starkey, and Fujita use Chapter 4 to examine several long-standing systematic issues of chelydrid turtles. The authors focus on the following questions using molecular data: i) Are *Macrochelys* and *Chelydra* sister taxa? ii) Does current taxonomy reflect the evolutionary diversity present in *Chelydra*? iii) Is the Asian big-headed turtle (*Platysternon*) allied with the Chelydridae? The authors do a good job explaining why these are important systematic questions and put forward satisfactory answers. The chapter ends with some taxonomic recommendations and identification of areas needing additional research.

Chapter 5, by Nigel West, covers respiratory and cardiovascular physiology. Much of the emphasis is on gas exchange and ties in nicely with chapter nine on overwintering.

Mahmoud and Alkindi review snapping turtle reproductive physiology in Chapter 6. Gonadal cycles and hormone levels in both male and female snapping turtles are discussed. Much of the information covered in this chapter is taken from papers co-authored by the senior author.

Chapter 7, by Spotila and Bell, is about thermoregulation and feeding biology. Much of the chapter is spent discussing thermoregulation in turtles generally and comparing snapping turtles to other turtle species. As in other chapters, I was struck by how little is known about snapping turtle thermal biology and the great need for further study in this field.

Robert Gatten, in Chapter 8, covers metabolism and energetics of eggs and turtles. Gatten does a good job showing the relevance of energy use to major life history characteristics such as incubation environment, sex determination, growth, and overwintering.

Ultsch and Reese discuss overwintering in Chapter 9. The adaptations needed to survive in low oxygen environments and at cold temperatures are fascinating and this chapter is a great overview of this topic. The authors also mention the importance of protecting hibernating turtles. This is wise advice particularly as commercial harvesters in Minnesota and other northern states are known to collect overwintering snapping turtles through holes in the ice.

Chapter 10, by Michael Ewert, is about embryos and incubation with a strong focus on energy utilization and latitudinal variation. Importantly, this chapter utilizes previously unpublished data in new analyses in a comparison of snapping turtle egg incubation from Tennessee and Minnesota. Ewart's results suggest a suite of physiological adaptations of snapping turtles eggs to the shorter growing seasons of northern latitudes.

Anthony Steyermark writes about snapping turtle growth patterns in Chapter 11. The chapter is generally written and serves as a good introduction to the importance of growth to individuals and species. Growth, and the factors affecting it, are discussed for both embryos and juvenile/adult stages. Like most chapters, there is a section on directions for future research.

Justin Congdon, Judith Greene, and Ron Brooks review the nesting behavior and reproductive ecology of female snapping turtles in Chapter 12. This chapter has some overlap with several other chapters in the book but it is different enough so that it doesn't seem repetitive. Additionally, much of the information presented in this chapter is unpublished having being collected at the long-term study sites of the authors: Savannah River in South Carolina; E. S. George Reserve in Michigan; and Algonquin Provincial Park in Ontario. This chapter is very well written and offers a clear and concise overview of snapping turtle life history and reproduction.

Chapter 13 by Ackerman, Rimkus and Lott overviews water relations of snapping turtle eggs. The authors state, "It is probable that what we think that we understand about the role and importance of egg and embryonic water exchange for reptile eggs rests largely on the study of the eggs of *C. serpentina*." If this statement is true then this chapter provides not only a thorough introduction to water exchange in snapping turtle eggs but in reptile eggs as a whole. The chapter is well written and does indeed offer a thorough and concise introduction and summary to this important field.

Snapping turtles have been important models in the study of temperature-dependant sex determination (TSD), the topic of Chapter 14 by Fred Janzen. Understanding the adaptive significance of TSD is key to understanding the evolution of sex-determining mechanisms and the maintenance of TSD. Janzen provides a thorough overview of these topics as well as some of the functional aspects of TSD. A comprehensive compilation of snapping turtle incubation data from the literature provides a sort of meta-analysis on the influence of temperature on hatchling gender. Janzen writes a concise introduction to TSD that will serve as an important entry into the field of sex determination in snapping turtles specifically and reptiles as a whole.

Ecology and physiology of hatchling turtles is outlined in Chapter 15. Michael Finkler and Jason Kolbe review in great detail what is known about snapping turtles in the period from hatching through the first year. The chapter highlights the interactions between hatchling turtles and their environment during hatching, overland migration from the nest to the water and finally, interactions once in the water. The topics covered in this chapter have similarities with other chapters in the book but, as with Chapter 12, it is not repetitive, and highlights the integrative nature of the volume.

Chapter 16 by David Galbraith examines population biology and population genetics of snapping turtles. The chapter is divided roughly into thirds, with a portion devoted to age estimations in snapping turtles, a section on life history characteristics and demography, and finally a thorough section on population genetics. Within the last section on genetics, Galbraith poses eight predic-

tions regarding snapping turtle genetic structure based on the snapping turtle's unique life history characteristics. These predictions provide a defined series of testable hypotheses to future researchers making this chapter one of the most useful in the whole book.

Chapter 17 by Don Moll and John Iverson covers geographic variation and life-history traits. The content is an extension of Iverson et al. (1997) and uses the data presented in that paper, as well as results of studies conducted since then, to examine how morphological and reproductive characteristics vary across the large geographic range of *C. serpentina*. Despite numerous studies involving snapping turtles, there is still much more work needed to fully understand the range of life-history variation and its possible causes.

The book appears well put together although the margins, particularly at the top of the page, are a bit tight. I noticed few print errors: one spelling mistake in the References section, on page 220, "ski" instead of "skin" in the title of Yntema 1974b; and "Brooks 1992," cited on page 169 in Chapter 16, is not listed in the Literature Cited. As mentioned before, figure 2.3 is too small and could have easily filled an entire page.

Overall the editors and authors did a good job integrating the subject matter to provide a very complete picture of snapping turtle biology. That said, some minor inconsistencies occur where a statement made in one chapter contradicts information presented in another. For example, in both chapters 5 and 16, *C. serpentina* is said to occur throughout North and Central America south to Ecuador. The first and fourth chapters of the book make clear that the Central and South American *Chelydra* are not *C. serpentina* but *C. acutirostris* or *C. rossignonii*. These mistakes appear to be oversights by the authors and editors and not a rejection of current snapping turtle taxonomy. There are additional inconsistencies in Chapter 1. Discussing relationships of the Chelydridae to other turtles, Ernst says "… all other extant cryptodirans are their sister group." While this relationship has been proposed, Chapter 4 makes a strong case that chelydrid turtles are nested well within the Cryptodira. Similarly, Chapter 1 states there are two fossil species of *Macrochelys* while Chapter 2 lists three species. Finally, Chapter 1 states that the earliest *Chelydra* fossil is from the Pliocene, citing Chapter 2 of the same volume, instead of the Miocene as correctly listed in Chapter 2.

One topic missing, sadly, is a chapter on conservation and management. While snapping turtles are relatively abundant throughout their range, they are harvested in large numbers in some areas (Brooks et al. 1988), suffer from high levels of road mortality (Steen and Gibbs 2004), and accumulate elevated levels of environmental contaminants (Helwig and Hora 1983; Ashpole et al. 2004). Snapping turtles are considered vulnerable in two U.S. states and two Canadian provinces (NatureServe 2008). Conservation and management are briefly mentioned in the chapters by Congdon, Greene, and Brooks (Ch. 12) and Galbraith (Ch 16), as well as the introduction by Whit Gibbons. Nonetheless, a dedicated chapter for reviewing the threats to snapping turtles and their management would have been a worthwhile addition.

Summarizing what we know about a species makes obvious our gaps in scientific knowledge. Publication of a book like *Biology of the Snapping Turtle* can help guide future research in filling those gaps. Most chapters in *Biology of the Snapping Turtle* have a section detailing potential directions for future research. Chelonian biologists should consult this volume when designing research plans involving snapping turtles, or any turtle species for that matter. One obvious gap in knowledge repeatedly mentioned throughout the book relates to intraspecific variation across the species' distribution. Almost all of the authors comment on how we only have data from a few populations, representing a fraction of the snapping turtle's continent-wide range. Additionally, many of these data are from the northern portions of the distribution. It is obvious after reading *Biology of the Snapping Turtle* that conducting research across the full range of the snapping turtle's distribution, particularly involving populations in the southern United States and Mexico, should be a priority.

Biology of the Snapping Turtle is a well-executed volume filled with useful information. The strong emphasis on physiology is particularly welcome and anyone conducting physiological research on reptiles and reptile eggs is advised to get this book. While the publisher's list price is a bit steep, wildlife managers, fisheries biologists, herpetologists, and vertebrate physiologists will find it a handy reference to this widespread turtle species.

Science and Conservation of Vernal Pools in Northeastern North America, edited by Aram J.K. Calhoun and Phillip G. de Maynadier. 2008. CRC Press, Boca Raton, Florida (www.crcpress.com). xxvii + 363 pp., 12 pp. pls. Hardcover. $US 99.95. ISBN 978-0-8493-3675-1.

AARON M. BAUER
Department of Biology, Villanova University
800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA
e-mail: aaron.bauer@villanova.edu

This is a comprehensive consideration of vernal pools of the Northeast—here defined as the area that was glaciated during the Late-Wisconsin glaciation (35,000–11,000 years B.P.) and bounded on the west by the forest-prairie interface and in the north by the current tree line. The region encompasses the states and provinces from Minnesota and Manitoba east to New England and the Atlantic provinces of Canada and south to the terminal moraines of New York, Pennsylvania, Ohio, Indiana, Illinois, and Missouri.

The book is divided into three sections dealing with 1) the physical (geomorphology, hydrology, remote and field identification of vernal pools), and 2) biological setting (flora and fauna) of vernal pools, and 3) aspects of conservation in the human modified landscapes that dominate in much of the region covered by the book. Each of the 16 chapters by 33 authors is self-standing, with its own set of references. The book is a companion to an earlier volume by Colburn (2004), which concentrated on the plants, invertebrates, and microorganisms of these wetlands. In contrast, this volume has a strong herpetological component, with five chapters (totaling 114 pages) devoted largely to amphibians and reptiles. In addition, the 12 color plates illustrating the book include eight images of vernal pool-associated amphibians and reptiles.

"Ecology and Conservation of Pool-Breeding Amphibians" by Semlitsch and Skelly deals with the life cycles, distribution, population and community dynamics, and spatial ecology of the 27 species that breed in the vernal pools of the northeast, along with the conservation implications of these parameters. Although only *Scaphiopus holbrookii* and *Rana sylvatica* (as well as *Pseudacris triseriata* in parts of its range) use vernal pools as their principle breeding habitats, nine of ten salamanders, including eight ambystomatids, *Hemidactylium*, and *Notophthalmus viridescens*, use them commonly.

In "The Importance of Vernal Pools to Reptiles, Birds, and Mammals," Joe Mitchell and colleagues report on the uses, mostly facultative, of vernal pools made by amniotes. Although as many as half of regional reptiles occasionally make use of these wetlands, only *Clemmys guttata*, *Emydoidea blandingii*, and, to a lesser extent, *Glyptemys insculpta* among the turtles, and *Nerodia erythrogaster* and *Thamnophis sauritus* among the snakes, can be considered to commonly use vernal pools and their edges for activities such as foraging, thermoregulation, nesting, and aestivation.

In "Population and Genetic Linkages of Vernal Pool-Associated Amphibians" by Gibbs and Reed, drift, inbreeding, extinction, and migration distance relative to the clustering of vernal pools are considered. Because of low population sizes and local fluctuations inbreeding and drift may be particularly important. The authors highlight the general lack of population structure data, which are necessary in order to develop intelligent conservation strategies.

The remaining herpetological chapters, "Conserving Vernal Pool Amphibians in Managed Forests" and "Spatial Tools for Conserving Pool-Breeding Amphibians," are grouped in the conservation section of the book. The first of these highlights the importance of forest management practices for conserving amphibians. It stresses the need for a high percentage of canopy cover to maintain amphibian abundance and the importance of complex life cycles and philopatry in planning tree harvesting operations in areas with vernal pools. This is particularly critical in areas such as Maine and New Brunswick, where forests cover more than 85% of the landscape.

The second chapter advocates a landscape species approach to conservation. Landscape species are those that require habitats in multiple ecosystems within a landscape in order to survive. Using the example of *Rana sylvatica* in Maine, the authors demonstrate how gap analysis can be used to identify focal landscapes of conservation concern where landscape elements of high value to amphibians intersect with human landscape elements that threaten amphibians.

Other chapters in this section of the book include those on conservation policy, chemical contamination, conservation in urbanizing environments, vernal pools as outdoor laboratories for education, and community-based conservation initiatives. The book concludes with a detailed subject index that also includes taxa discussed, but only by common name (except in the case of certain key plants, such as *Sphagnum*).

Vernal pools are disproportionately significant in ecological terms because of the high diversity of organisms they support. Their small size is a double-edged sword; their ubiquity in the glaciated landscape, as well as their manageable dimensions makes them especially amenable to study, but also leaves them vulnerable to destruction and in particular need of conservation. Amphibians, because of both their varied uses of vernal pools and associated habitats during the course of their complex life cycles and their sensitivity to environmental perturbations, have been particularly valuable in the interpretation of complex ecological interactions in vernal pools and influential in the practical implementation of conservation strategies in the glaciated landscapes of the Northeast.

Collectively, the contributions in this volume present the physical and biological data that explain the structure of vernal pool communities and explore the ways in which an understanding of vernal pools can inform land, water, and wildlife management decisions and guide conservation priorities. Although of broad relevance to herpetologists, ecologists, and other biologists working in the northeastern United States and eastern Canada, the high cost of the book may limit its distribution. However, it will be of particular value to natural resource managers and conservation biologists,

for whom the investment may well be justified.

e-mail: dlea886@tamu.edu

Big Bend National Park (BBNP) is not only the largest national park in Texas, it is also located in one of the most herpetologically diverse regions of the state (Owen 1989). Available literature regarding field identification of the amphibians of BBNP can be found in two distinct categories—locally specific and state or national. Locally specific nature guides appeal to naturalists with general interests in the Big Bend region but often are not descriptive enough with respect to amphibian lifestyles and distributions (e.g., Wauer and Fleming 2002), whereas state or national guides lack local appeal and are too generalized to provide relevant information regarding regional variation or natural history (e.g., Garrett and Barker 1987; Conant and Collins 1998). This leaves visitors, biologists, and wildlife enthusiasts to identify what they see at Big Bend with suboptimal, or even misleading (e.g., Eifert and Eifert, 2007), nature guides. *Frogs and Toads of Big Bend National Park* provides a welcome alternative.

Few national parks have received such taxon-specific attention with respect to any group of organisms, let alone amphibians. BBNP, and West Texas in general, has lower amphibian diversity than eastern portions of the state (Owen 1989). Regardless, the species present in BBNP include some interesting and unique anurans. Considering the remoteness of this region, the diversity of the taxa present in the park, and the book's applicability to its surrounding vicinity, this guide is fully warranted. Specialized regional field guides like this one will provide useful information to park and regional visitors, naturalists, and herpetologists, and have the potential to spur the production of more locally specialized field guides.

It is obvious that a great deal of care went into designing the layout of this book from cover to cover. The book is field-ready—it is extremely easy to handle (it could fit in a big pocket) and the plasticized soft-cover binding can handle the elements. The contents go far beyond those of most other field guides. The authors present this guide as a culmination of a seven-year amphibian survey in BBNP. Every species account provides identification tips and natural history, as well as a brief description of where in the park the species has been found. The authors describe 11 of the 12 known amphibian species from the park in great detail—*Hyla cinerea*, a recent addition to the park checklist (Leavitt et al. 2007), is excluded. The traditional field guide format of species accounts is abandoned to describe recent population trends and life history traits unique to these desert amphibians.

Many high-quality color photographs are presented for each species, although a few are used more than once. Many of these species have variable patterns and unique behavioral or ecological characteristics, and a few more photographs representing this morphological and biological diversity could have been provided. The photos work well in conjunction with the authors' useful dichotomous key to the species, greatly facilitating field identification of the frogs and toads of BBNP. Specialized terms relating to amphibians and the desert environment that are used in the key and elsewhere in the book are defined in a two-page glossary. It is unfortunate that page numbers of species accounts are not provided in the key, as this would simplify the identification process. Another minor issue is that authors refer to *Spea multiplicata* as the Mexican Spadefoot in the text and as the New Mexico Spadefoot in the key. Although such minor problems hardly detract from such a well-executed book, they should be considered for improvement in future editions. The book closes with a literature referenced section—for the studious, and an index—for the forgetful.

Overall, *Frogs and Toads of BBNP* has a very strong appeal for both scholars and naturalists. Throughout the species accounts the authors integrate their knowledge of, and concern for, conservation of BBNP anurans with field identification basics, providing a field guide that will be a great addition to the library of anyone interested in Big Bend or the frog fauna of the southwest.

PUBLICATIONS RECEIVED

The Frog-Biting Midges of the World (Corethrellidae: Diptera), by Art Borkent. 2008. Zootaxa 1804:1–456. Online publication (www.mapress.com/zootaxa/). ISBN 978-1-86977-211-3 [also available in paper copy edition].

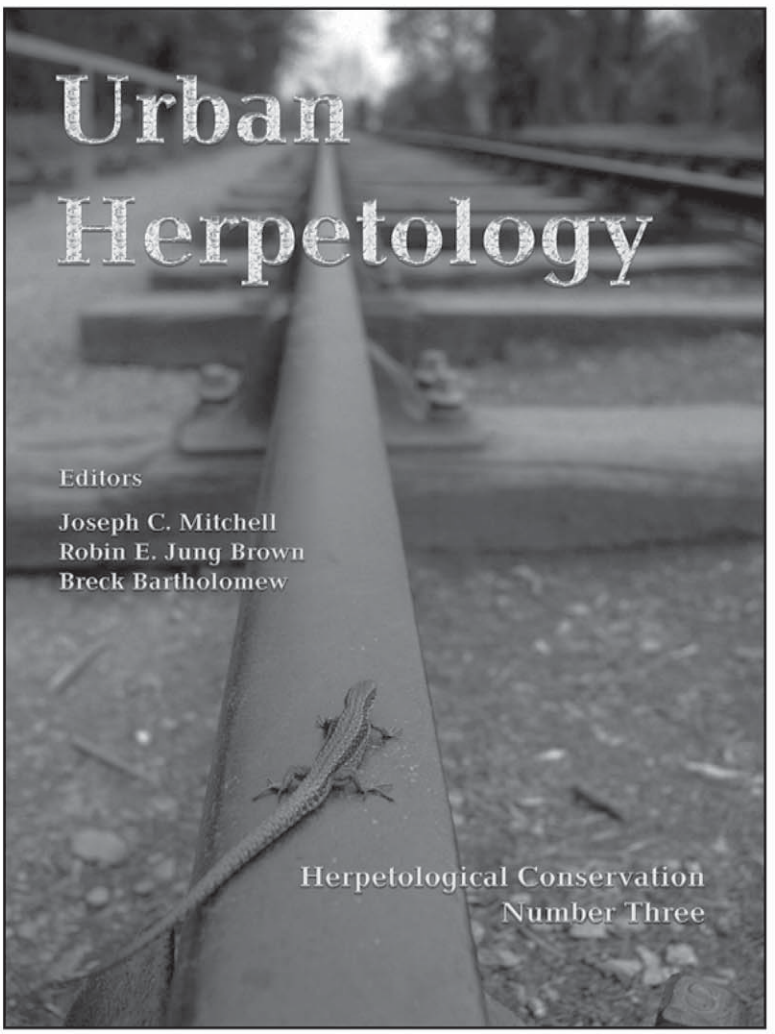
This monograph on dipteran insects is of direct relevance to herpetologists because females of corethrellid midges are attracted by the calls of male frogs and feed on their blood. Immature stages of the midges may be associated with terrestrial habitats or phytotelmata. At least some species are known to transmit *Trypanosoma* to the frogs they feed upon. This major treatment of the group recognizes 97 extant species—52 of them new, and seven fossil forms, of which two are described as new. In addition to species accounts and descriptions *per se*, the work includes a cladistic analysis of the Corethrellidae as well as maps and keys for all of the recognized taxa. Biogeography of the group should be of special interest to herpetologists because of the close association between fly and midge—at least some taxa are host-specific in their feeding preferences. The author concludes that the frog feeding lifestyle of these insects dates from the early Cretaceous and considers that some patterns of affinity and distribution are reflective of Gondwanan origins. Abstracts of this, as well as many taxonomic papers and monographs dealing with amphibians and reptiles (as well as all other animal groups), can be accessed at the Zootaxa website. Some Zootaxa publications are open access, others are available for purchase in hardcopy or electronically through personal or institutional library subscription.

Don't Touch That! The Book of Gross, Poisonous, and Downright Icky Plants and Critters, by Jeff Day. 2008. Chicago Review Books (available through Independent Publishers Group; www.ipgbook.com). [iv] + 108 pp. Softcover. US $9.95. ISBN 978-1-55652-711-1.

This book is intended for children aged seven to nine. It presents for its young readers an overview of the poisonous, venomous, and otherwise dangerous plants and animals of North America (with vignettes dealing with some exotic taxa). The book is humorously written and illustrated by numerous cartoons depicting the relevant wildlife and their effects on humans. The information presented is fundamentally sound and clearly presented. The author, who is both a pediatrician and cartoonist, has creatively taken advantage of children's love of all things that most adults find disgusting to present a quite practical primer. In addition to amphibians and reptiles, the book considers plants (poison ivy, stinging nettle, mushrooms, etc.), insects (bees, wasps, ants, fleas, lice, mosquitoes), spiders (as well as scorpions and ticks), mammals (porcupines and skunks as well as domestic and wild mammal bites and their associated complications—rabies, tetanus, etc). The herpetological section of the book discusses amphibian skin secretions in general, *Salmonella*, pit vipers, and gila monsters. It provides basic information about the identification of venomous snakes, the venom apparatus, effects of venom on the body, snakebite treatment, production of antivenin, and tips for avoiding snakebites. The philosophy of the book is that learning about potentially dangerous organisms in their surroundings will allow kids not only to avoid trouble but to confidently explore and enjoy nature. *Don't Touch That!* should make a good gift for budding naturalists.

HERPETOLOGICAL CONSERVATION VOLUME 3

URBAN HERPETOLOGY



Edited by Joseph C. Mitchell, Robin Jung Brown, and Breck Bartholomew

Foreword by John M. Marzluff

Afterword by Michael J. Lannoo

Illustrations by Carel P. Brest van Kempen

120 contributing authors from around the world

Herpetologists in some parts of the world, notably Europe and Russia, have long engaged in studies of amphibians and reptiles in urban environments. Urbanization is progressing at such a rapid pace that herpetofaunal populations are becoming extirpated and species continue to decline. This book shows how studies of amphibians and reptiles in urban systems have much to offer scientists, conservation biologists, and land managers, and how important conservation, education, and management efforts are to the continued persistence of amphibians and reptiles in urban settings.

40 chapters and 13 case studies grouped into eight sections:

Direct and Indirect Effects of Habitat Loss and Alteration

Effects of Roads, Trails, and Railroad Tracks

Chemical and Light Pollution

Stormwater Ponds, Swimming Pools, Urban Lakes, and Golf Courses

Introduced Species, Urbanophiles, and Urbanophobes

State, Regional, and Country Reviews

Management, Regulations, and Conservation

Education, Citizen Involvement, and Conservation

Specifications: 592 pages, 8½ × 11 inches, numerous black and white illustrations, figures, and tables, clothbound with a dust-jacket.
ISBN 978-0-916984-79-3.
To be published December 2008.

PRICES AND SHIPPING COSTS: Pre-publication to SSAR members US$60.00 (valid through 28 February 2009); Institutions, non-members $75.00 • *Shipping*: shipping fees are not included and will be charged at cost.

SEND ORDERS TO: Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158-0517, USA (*telephone and fax*: 1-801-562-2660; *email*: SSAR@herplit.com). A New Facsimile Reprint from the Society for the Study of Amphibians and Reptiles

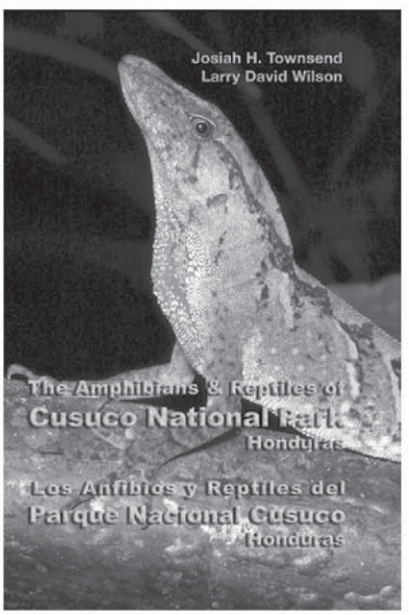
THE LIFE AND HERPETOLOGICAL CONTRIBUTIONS OF
AUGUST FRIEDRICH SCHWEIGGER (1783–1821)

August Friedrich Schweigger (1783–1821) was best known to the world as a botanist, but his contributions to herpetology were of great importance. In his major work, *Prodromus Monographiae Cheloniorum*, published in Latin in 1812, Schweigger provided a comprehensive overview of the chelonians of the world, giving accounts for 84 nominal taxa in six genera. Of these, 24 were described as new; 14 of these species remain valid today. Among the taxa authored by Schweigger are such well known species as *Melanochelys trijuga*, *Pelusios castaneus*, *Mauremys leprosa*, *Podocnemis expansa*, and *Chersina angulata*, as well as the generic name *Chelydra*. In addition to this 157 page paper, the facsimile includes Schweigger's later (1814) chelonian monograph (66 pages), with some corrections and changes to his 1812 paper, and a never-before published manuscript (72 pages) from 1809, representing the earliest version of his classification of turtles.

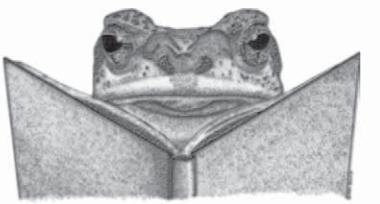
The facsimiles are accompanied by a detailed 79 page bilingual (English/French) introduction by Roger Bour. It details Schweigger's early research in Paris, his academic successes in East Prussia, and his tragic murder in Sicily while on a collecting trip. Taxonomic and bibliographic comments on the reprinted works are also provided, as is a 200+ word Latin-English-French lexicon to facilitate use of the original Latin papers.



Specifications: 390 pages, 6 x 9 inches, 8 black and white figures, clothbound. ISBN 978–0–916984–78–6. To be published October 2008.

PRICES AND SHIPPING COSTS: US $30 (10% discount to SSAR members) • *Shipping*: shipping fees are not included and will be charged at cost.

SEND ORDERS TO: Breck Bartholomew, P.O. Box 58517, Salt Lake City, Utah 84158-0517, USA (*telephone and fax*: 1-(801)562-2660; *e-mail*: ssar@herplit.com). Please make checks payable to "SSAR." Overseas orders must be paid in USA funds using a draft drawn on American banks or by International Money Order. Orders may also be charged to MASTERCARD, VISA, AMERICAN EXPRESS, or DISCOVER CARD (Please provide the account number and card expiration date). SSAR membership information and a complete list of all Society publications can be obtained on request to Mr. Bartholomew.



The Amphibians & Reptiles of Cusuco National Park, Honduras
Los Anfibios y Reptiles del Parque Nacional Cusuco, Honduras

Josiah H. Townsend and Larry David Wilson

Cusuco National Park in northeastern Honduras is home to 50 species of amphibians and reptiles, nine of which are endemic to the park. This book, in English and Spanish, is an in-depth guide to the park's herpetofauna.

Specifications: xiv, 322 pages, 6 x 9 inches. Hardcover (ISBN: 978-1-932871-12-8) $44.95 + postage.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution or Natural History notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order form will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor. Regarding missing or damaged issues, please notify *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA (tel. 785/843-1234 or e-mail: herps@allenpress.com).

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 840		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

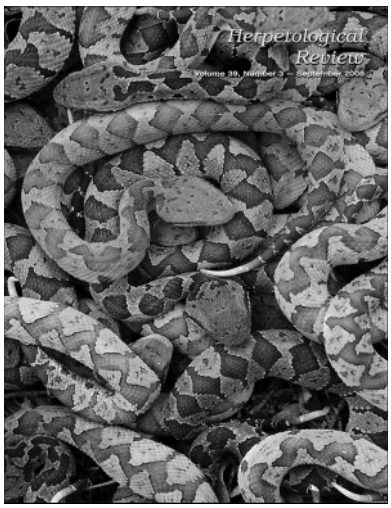
www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2008 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.



To join SSAR or to renew your membership, please visit the secure online Allen Press website:

Future Annual Meetings

2009 — Portland, Oregon, 22–27 July (with ASIH, HL)
2010 — Providence, Rhode Island, 7–12 July (with ASIH, HL)
2011 — Minneapolis, Minnesota, 6–11 July (with ASIH, HL)

About Our Cover: *Atropoides mexicanus*

The Central American Jumping Viper, *Atropoides mexicanus*, is one of five species assigned to the genus *Atropoides*. Exceptionally stout snakes with heavily keeled scales, the taxonomy of this morphologically similar group of pitvipers is not well resolved. Recent phylogenetic analysis suggests undescribed taxonomic diversity within the genus (Castoe et al. 2005. Molecular Phylogenetics and Evolution 37:881–898). Ranging from southern Mexico to central Panama, *A. mexicanus* is essentially a sedentary, mostly terrestrial species inhabiting tropical moist to wet forests at 40–1600 m in elevation. Adults average 50–70 cm TL, but can occasionally reach lengths of over 90 cm.

What's in a name? Throughout Central America this species is commonly referred to as "Mano de Piedra," in reference to its resemblance to a stout implement used in grinding corn in the making of tortillas. The vigorous striking ability of this species has led to grossly exaggerated claims that it is capable of launching itself a distance equal to or greater than to its own body length, hence the common English name of "Jumping Viper." Even the late Raymond Ditmars suggested that this snake may be able to jump as much as a yard if given "good purchase to lurch its coils" (Ditmars 1931. Snakes of the World. Macmillan, New York. 270 pp.). In reality, the striking distance of this snake might possibly cover a distance of half of its own body length.

Solórzano (1989. Revista Biología Tropical 37[2]:133–137) found that *A. mexicanus* reproduction in Costa Rica was distinctly seasonal depending on geography. Females from the Pacific versant gave birth in the late dry to early rainy season (March–June), whereas females from the Atlantic versant and areas of the Central Plateau gave birth during the rainy season (August–November). From five to thirty-seven young have been reported in single litters, with the smallest gravid female being just 38 cm in total length (March 1929. Bulletin of the Antivenom Institute of America 3[1]:27–29).

The 22 juveniles featured on the cover were born on 31 August 2007 from a captive 65 cm (TL) Honduran female. Considerable polymorphism exists even within single litters, as evidenced by the variation in color in these juveniles. Young are reported to feed primarily on orthopterans and lizards in the wild (Campbell 1998. The Amphibians and Reptiles of Northern Guatemala, Yucatán, and Belize. University of Oklahoma Press, Norman. 367 pp.); however, captive born individuals will readily consume small mice. Although born with cream-to-yellow tail tips, caudal luring has not been reported in this species.

The rather calm juveniles were photographed using a Nikon D50 digital SLR camera with a Sigma 90mm macro lens the day following their birth. The image was recorded using natural light with fill flash from the camera. Photographer **R. Michael Burger** has been involved with amphibians and reptiles for four decades. His articles have appeared in a variety of North American and European publications, including recent issues of *Zoo Biology*, *Herpetological Journal*, *Reptiles Magazine*, as well as in the recently published book *Biology of the Boas and Pythons*. Michael lives with his understanding wife on a small ranch in Mabank, Texas.

Kennedy Student Award Committee

The Kennedy Award Committee (Carl Anthony, Bill Lutterschmidt, Terry Schwaner, Wayne VanDevender, Lynnette Sievert, Chair) has completed its work for Volume 41 of the *Journal of Herpetology*. The Committee has selected "Phylogenetic and Systematic Study of the Genus *Bombina* (Amphibia: Anura: Bombinatoridae): New Insights from Molecular Data" by **Guohua Yu**, Junxing Yang, Mingwang Zhang, and Dingqi Rao (Vol. 41:365–377). The Kennedy Award carries with it a cash prize of US $200 or the winner's selection of any SSAR publications valued at twice that amount.

The committee invites all student members of the Society to submit their work to the Journal, and encourages regular members who supervise the work of students to draw this award to the attention of those students.

Annual Report (2008)
Grants-in-Herpetology Committee

An award in the amount of US $500 was made to each of the following individuals:

Conservation.—Sara M. Maxwell, University of California, Santa Cruz. Project title: "Conservation of olive ridley sea turtles in Central Africa."

Field Research.—Sarah Becker, Southern Illinois University. Project title: "Hanging out with cool frogs: Microhabitat temperatures' effect on disease susceptibility."

Laboratory Research.—William T. McLamb, Florida Institute of Technology. Project title: "Molecular and physiological characterization of infrared thermosensation in boid and crotaline snakes."

Travel.—Kyna M. Hogg, University of North Dakota. Project title: "Landscape level distribution and effects of landscape configuration and habitat on several anurans of three river drainages in North Dakota."

International.—Michael Hailu, Addis Ababa University, Ethiopia. Project title: "Status, social organization and conservation of the vulnerable African spurred tortoise, in East Rift Valley, Ethiopia."

Education.—Mike Hickel, Rolling Hills Wildlife Adventure, Salina, Kansas. Project title: "Public Herpetological Field Guide."

2008 Grants-in-Herpetology Committee.—Co-chairs: Erik R. Wild and Josh Kapfer. Reviewers: Jeffrey Parmelee, Rich Seigel, Vince Cobb, Brian Smith, Brian Greene, Matt Rowe, Rebecca Christoffel, Rich King, David Wake, Stephen Richter, Jerry Husak, Michael Pauers, Chirstopher Beachy. SSAR congratulates the 2008 GIH recipients and thanks the committee members for their efforts.

NEWSNOTES

Amphibian Ark's Amphibian Population Management Guidelines Released

In December 2007, a group of population biologists, amphibian husbandry experts, and software developers gathered for two days in San Diego, California. The goal of the workshop was to develop a series of population management guidelines that would cover all species of amphibians, and be useful for a wide-ranging audience, from population biologists to amphibian breeders.

The *Amphibian Population Management Guidelines* are now available for download at: http://www.amphibianark.org/

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

3–4 October 2008—Annual Meeting of the Gopher Tortoise Council, Jekyll Island, Georgia, USA. Refer to meeting announcement above.

7–9 November 2008—35th Annual Meeting of the Kansas Herpetological Society, Wichita, Kansas, USA. Information: http://www.cnah.org/khs/AnnualMeetingInfo.html.

24–29 November 2008—VIII Latin-American Congress of Herpetology (VIII Congreso Latinoamericano de Herpetologia), Topes de Collantes, Sancti Spiritus, Cuba. Information: Roberto Alonso Bosch (e-mail: 8voclah@fbio.uh.cu or ralonso@ecologia.cu).

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Adaptive Significance of Temperature-Dependent Sex Determination

It has been known for some time that for many species sex is determined by the temperature that the eggs are exposed to during development. It has long been thought that temperature-dependent sex determination (TSD) is advantageous when the temperature experienced during development differentially influences the fitness of males and females. However, experiments to test for the adaptive significance of TSD have been elusive. By treating the eggs of Jacky Dragons (*Amphibolurus muricatus*) with hormones, the authors of this study generated males at temperatures that would normally produce females. Some males generated under typical male-producing temperatures were also treated with the hormones to ensure that the hormones themselves had no effect on fitness. They then compared the fitness (measured in reproductive output) of males generated under the different temperatures over the next 3.5 years. As predicted, males produced under typical male-generating conditions exhibited a significantly higher fitness than the hormone-treated males.

Warner, D. A., and R. Shine. 2008. The adaptive significance of temperature-dependent sex determination in a reptile. Nature 451:566–568.

Impact of Saltcedar Removal on Lizards

Saltcedar (*Tamarax* spp.) has invaded many riparian ecosystems in the American Southwest, often to the detriment of native fauna and flora. However, to date, no study has documented the effects of saltcedar removal on reptiles. In this study, the authors attempted to document the impact of saltcedar control methods on communities of lizards along the Rio Grande in central New Mexico, habitats historically dominated by cottonwood (*Populus deltoides*). The relative abundances of the six most frequently encountered lizard species was monitored at twelve sites for seven years. For every three sites that experienced saltcedar removal, one was left untreated as a control. Analyses revealed an increase in abundance for two species and no significant decrease in abundance for any species after non-native plant removal. The authors suggest that removing non-native understory plants allows more opportunities for lizards to bask in areas where light penetrates the canopy.

Bateman, H. L., A. Chung-MacCoubrey, and H. L. Snell. 2008. Impact of non-native plant removal on lizards in riparian habitats in the southwestern United States. Restoration Ecology 16(1):180–190.

Effects of Thyroxine on Salamander Metamorphosis

Many studies have examined amphibian metamorphosis; however little is known about the patterns of gene expression that transpire during salamander metamorphosis. In this study, the authors attempted to document how thyroxine (T_4; a thyroid

hormone) concentrations affect metamorphosis and gene expression in the Mexican Axolotl (*Ambystoma mexicanum*), an obligate paedomorph that can be induced to metamorphose when exposed to thyroid hormones in the laboratory. Individuals were exposed to two different concentrations of T_4 and the subsequent metamorphosis was observed. Different concentrations of T_4 were found to affect the timing of the onset of the metamorphosis but not the duration. While many of the genes found to be expressed during metamorphosis were also known to be activated during anuran metamorphosis, there were also some differences, highlighting the importance of studying metamorphosis in diverse amphibian taxa.

PAGE, R. B., S. R. VOSS, A. K. SAMUELS, J. J. SMITH, S. PUTTA, AND C. K. BEACHY. 2008. Effect of thyroid hormone concentration on the transcriptional response underlying induced metamorphosis in the Mexican axolotl (*Ambystoma*). BMC Genomics 9:78 (17 pp.).

Use of Forked Tongue for Edge Detection in Snakes

It has been hypothesized that the deeply forked tongue of some squamates functions as a chemical "edge detector," where cues gathered by each tine are kept separate to provide the central nervous system with two points of lateral odor assessment via the vomeronasal nerve. While following a chemical trail, one tine can be on the trail, the other off, and such differential information prompts the snake to turn back to the trail. It has been shown that in snakes, complete disruption of the vomeronasal nerve severely impairs the ability to track prey; however, no study has attempted to unilaterally disrupt the vomeronasal nerve to determine the impact on tracking ability. The authors of this study compared the tracking ability of Western Rattlesnakes (*Crotalus oreganus*) before and after severing one side of the vomeronasal nerve. The authors found no change in the seven separate trailing parameters measured. They suggest instead that deeply forked tongues may represent a chemosensory specialization to increase odor-sampling area.

PARKER, M. R., B. A. YOUNG, AND K. V. KARDONG. 2008. The forked tongue and edge detection in snakes (*Crotalus oreganus*): An experimental test. Journal of Comparative Psychology 122(1):35–40.

Massive Scale Turtle Farming in China

As the demand for turtle products has increased over the past 20 years, entrepreneurs in China have initiated large-scale commercial breeding facilities for profit. However, due to the secrecy of these operations, it has been difficult to fully appreciate the magnitude of Chinese turtle farming, and it is often assumed that most turtles in food markets and the pet trade come from the wild. Therefore, understanding the scale and scope of Chinese turtle farms is an important step towards understanding China's role in the Asian turtle crisis. The authors surveyed Chinese turtle farms with questionnaires in 2002 that included questions about which species were being farmed and their estimated annual yield. The results indicated that most native species of freshwater turtles are bred in Chinese turtle farms. Additionally, based on the responses and accounting for the percentage of farms that failed to respond, the authors estimate that the Chinese captive turtle trade generates annual revenue of US $1.3 billion. They stress that these extrapolations are conservative estimates because most farms operate illegally. Finally, the authors state that the farms do not serve as potential conservation resources and instead advocate the establishment of protected natural areas to preserve the few remaining populations of wild Chinese turtles.

HAITAO, S., J. F. PARHAM, F. ZHIYONG, H. MEILING, AND Y. FENG. 2008. Evidence for the massive scale of turtle farming in China. Oryx 42(1):147–150.

Amphibians Do Not Follow Bergmann's Rule

Bergmann's Rule, the pattern where organisms tend to be larger in cooler climates, has historically been thought to apply to endothermic and possibly ectothermic vertebrates, including amphibians. The authors tested this hypothesis by measuring 96,996 adult *Plethodon* salamanders from the eastern United States, belonging to 40 species, 3974 populations, and 3213 geographic locations. Typical adult body size and mean climate metrics were generated for both species and populations within species. Relationships between latitude and size were examined at both the inter- and intraspecific levels. The authors accumulated data from other studies of salamanders, frogs, and caecilians to look for Bergmann's Rule at higher levels. Of the 40 *Plethodon* species examined, only 3 exhibited a pattern concordant with Bergmann's Rule. Additionally, no relationship was found between body size and temperature among species of *Plethodon*. Finally, the meta-analysis revealed no support for Bergmann's Rule at either the order (Caudata) or class (Amphibia) levels.

ADAMS, D. C., AND J. O. CHURCH. 2008. Amphibians do not follow Bergmann's Rule. Evolution 62(2):413–420.

Character Clines Across a Recent Secondary Contact Zone in a Hispaniolan *Ameiva*

Within species, character clines at areas of secondary contact between morphologically differentiated lineages are maintained by the relative strengths of endogenous (selection against hybrid genotypes) and exogenous (differential selection across an environmental gradient) forces. While they superficially resemble each other, clines maintained by exogenous factors

should be strongly correlated with an ecotone (a transitional area between two ecosystems), while clines maintained by endogenous factors should be independent of the environment and instead display spatial clustering. The author examined a secondary contact zone in the teiid *Ameiva chrysolaema* that occurs near an environmental transition zone that runs east–west along the southern coast of Hispaniola. Morphological (measurements and scale counts; treated separately), mitochondrial DNA, nuclear DNA, and climactic data were collected from nine localities across the ecotone. A canonical variates analysis was performed on the measurement data and mean values were generated for all data types for each locality. The means were then plotted against distance along the transect and tested for concordance. The analyses revealed that the clines were not coincident, with the mitochondrial DNA cline being located quite far from the morphological and nuclear DNA clines. Additionally, the shape and location of the scale cline is coincident with the environmental data cline. Therefore, it is likely that the transition zone is primarily maintained by exogenous factors and there is little selection against hybrid genotypes.

GIFFORD, M. E. 2008. Divergent character clines across a recent secondary contact zone in a Hispaniolan lizard. Journal of Zoology 274:292–300.

Urosaurus nigricaudus Phylogeography

Historically, maternally-inherited mitochondrial (mt)DNA has been relied upon to infer intraspecific relationships; however, a growing importance has been placed on incorporating bipaternally-inherited nuclear DNA in phylogeographic analyses. In this study, the authors compared a mtDNA phylogeny generated in this study to previously published allozyme data in an attempt to elucidate the historical biogeography of the Black-tailed Brush Lizard (*Urosaurus nigricaudus*), a species that ranges throughout Mexico's Baja California peninsula. The existing allozyme data suggest moderate genetic divergences exist along the peninsula, with the deepest divergence occurring at mid-peninsula. Many researchers have attributed the various genetic breaks observed along the peninsula in this and other codistributed taxa to seaways that in the past have isolated northern and southern populations. The recovered mtDNA breaks were found to be discordant with respect to the allozyme data, with the deepest genetic break at the southern end of the peninsula. This incongruence is interpreted as ongoing gene flow following a past vicariant event, possibly in conjunction with sex-differential dispersal patterns.

Sphenodon Tail Autotomy

Tail autotomy occurs in most major Squamata lineages as well as Rhynchocephalia (*Sphenodon*). However, relative to squamates, little attention has been paid to tail autotomy and regeneration in rhynchocephalians. In this study, the authors examined > 200 preserved, skeletonized, and live *Sphenodon* in an attempt to characterize the nature of tail-loss and regrowth in this taxon. Their anatomical findings regarding tail autotomy in general, and in particular tail loss via intravertebral autotomy, largely corroborate previous studies. Interestingly, unlike the typical condition in squamates, both the frequency of tail autotomy and the length of intact tail was found to be equivalent in both sexes. As is common in squamates, left-side dominant individuals showed statistically elevated injury rates, including rates of tail autotomy. While the precise cause of this difference between left- and right-side dominant individuals in injury rate is unknown, the authors suggest that it is potentially related to escape capacity, in particular, speed. Additionally, tail-keeping and tail-losing males exhibited morphological differences echoing the sexual dimorphism observed between males and females, with tail-losing males resembling females.

SELIGMANN, H., J. MORAVEC, AND Y. L. WERNER. 2008. Morphological, functional and evolutionary aspects of tail autotomy and regeneration in the 'living fossil' *Sphenodon* (Reptilia: Rhynchocephalia). Biological Journal of the Linnean Society 93:721–743.

Lungless Frog Discovered in Borneo

Until recently, the only extant tetrapods known to have undergone a complete loss of lungs belonged to two salamander families and a single species of caecilian. The authors describe the first species of lungless anuran, *Barbourula kalimantanensis* (Discoglossidae), recently discovered in the highlands of Borneo. This species, which inhabits cold, fast-flowing streams, was initially known from two specimens collected in the 1970s and 1980s. The original collection locality was subsequently rendered uninhabitable by illegal gold mining operations. A recent expedition rediscovered the species upstream from the original locality. Examination of the additional specimens led to the discovery of its lack of lungs. This loss of respiratory structures extends to the loss of the glottis, allowing for an enlarged esophageal opening. An anatomical examination of the only other member of the genus, *B. busuangensis* from the Philippines, revealed an intact and functioning respiratory system. As its habitat is rapidly being degraded, immediate actions must be undertaken to ensure the survival of this enigmatic aquatic frog.

and
RICHARD SHINE
Biological Sciences, University of Sydney, NSW 2006, Australia
e-mail: rics@bio.usyd.edu.au

Dr. Rajkumar S. Radder, popularly known as 'Raju,' passed away on 31 May 2008 due to cardiac arrest at his home at Mulawad (India) at the age of 34. Raju was born in a small village in the Bijapur district of Karnataka State, India. He was the second of four children of Mr. Shivappa R. Radder, a retired high school Head-Master, and mother Anusuya. Raju was schooled at his village and obtained first place in the final secondary school public examination in the district. During his school days, Raju was active in a variety of extracurricular aspects that included participation in Scouts and Guides. Indeed, Raju received an award as the Best Scout, at state level. He was also an accomplished and enthusiastic cricketer.

Raju obtained his bachelor's degree in science at Bijapur and joined Karnatak University, Dharwad, India in 1994 for his Master's degree in Zoology. His professors recall Raju as a very impressive student, always eager to learn diverse aspects of biology. Raju completed his degree, with top ranking, in the year 1996. He remained in the same department for his doctoral work, under the supervision of Prof. B. A. Shanbhag and with Prof. S. K. Saidapur as co-guide. Raju conducted original research on the garden lizard, *Calotes versicolor* and discovered many interesting phenomena. For example, he found embryonic diapause, and an ability for long-term oviductal retention of eggs (up to 6 months: Radder et al. 1998). Raju also identified a possible mechanism for prolonged egg retention (maternal selection of lower body temperatures). He also explored and refined a wide range of methodologies, including manipulation of egg and clutch sizes by "allometric engineering" methods.

As well as his facility at laboratory studies, Raju enjoyed working in the field—even under difficult conditions. He conducted pioneering demographic studies on the fan-throated lizard, *Sitana ponticerana* and the rock lizard, *Psammophilus dorsalis* (Radder et al. 2005; Shanbhag et al. 2003). Raju began publishing papers in major international journals, and soon achieved significant national recognition as an upcoming herpetologist and evolutionary biologist. He was honored with the prestigious 'Young Scientist Award' by the Indian Science Congress (2002) and the 'Young Scientist Medal' by the Indian National Science Academy, New Delhi (2003). These are the two most prestigious such awards in India, and winning both was a remarkable achievement.

Raju rapidly built up an international as well as national reputation. In 2001 he approached Rick Shine at the University of Sydney about postdoctoral studies; and in 2003 Raju obtained a postdoctoral position funded by the Australian Research Council, to work on the adaptive significance of sex-determining systems in lizards. Raju arrived in Sydney early in 2004, and was employed by that institution until his untimely death in 2008. During his time at the University of Sydney, Raju initiated a wide range of collaborative projects with many people and on a diverse array of topics. Although the central theme of his research was sex determination, he found time to collaborate in studies on embryonic heart rates, ovarian morphology, yolk steroids, sex-based hatching asynchrony, the role of residual yolk for hatchling lizards, and the evolutionary significance of communal nesting (e.g., Radder 2007; Radder & Shine 2006, 2007a,b,c,d; Radder et al. 2007a,b,c, 2008a,b,c). All of these studies resulted in publications in major journals. Rick recalls a meeting of his research group, not too long after Raju first arrived, where Rick asked his people to briefly summarize their current projects. Just about everyone—students, postdocs, and research assistants—finished their summaries with "And also, Raju and I are doing a small study on …." The combination of Raju's infectious enthusiasm, his creative thinking, his willingness to discuss any aspect of science, his superb technical skills, and his mastery of a diverse array of analytical techniques, made him an extraordinary collaborator.

Raju's central project at the University of Sydney was to explore the complex sex-determination mechanism of a montane scincid lizard species. He showed that the conventional

division into "genetic sex determination" and "environmental sex determination" simply didn't work. These lizards have heteromorphic sex chromosomes (males are XY, females XX) but remarkably, incubation temperatures also influence offspring sex. Using genetic markers developed in collaboration with researchers at the University of Canberra, Raju's work demonstrated unambiguously that low incubation temperatures—temperatures often recorded in natural nests at high elevations—could turn genetically female offspring into phenotypic males (Radder et al. 2008c). He also pioneered methods for transferring yolk from one egg to another, and found strong evidence that such yolk transfer could determine the sex of the offspring: a truly novel sex-determination system. It is truly tragic that, having come so far on the path to understanding that system, Raju never had the chance to put the final pieces of the puzzle into place.

Through his time in both India and Australia, Raju was a wonderful colleague. A truly gentle human being, always respectful and polite, Raju nonetheless had a delightful sense of humor. At one conference of the Australian Society of Herpetologists, a particular delegate insisted on tapping away noisily at his laptop computer during student talks. Raju was deeply offended by this rudeness, so arranged for he and several friends to bring their laptops to that delegate's own talk—and to sit in the front row, all tapping away noisily, throughout the presentation. Raju had a superb skill at getting his point across without confrontation.

One of Raju's most impressive qualities was his ability to transcend cultural barriers in the course of his career in international science. For a man who grew up in a small village in India, Raju's ease in mixing on the international stage was truly impressive. During his time at the University of Sydney, Raju not only worked closely with people from many countries, but enthusiastically enmeshed himself in an Australian culture that at times must have seemed truly bizarre. During summers he spent many Sunday afternoons at a hotel near the University, watching cricket on TV and talking for hours with the local old-timers about their lives and experiences.

In his short life, Raju touched many of us very deeply. We have no doubt that he would soon have risen to be an international leader in his field, and his death is a great loss to evolutionary biology in general, as well as to herpetology in particular. We are enormously saddened at his death, but feel privileged to have had the opportunity to learn and laugh by his side.

A more detailed account of Raju's achievements, and a list of his publications (with downloadable PDFs) is available via the website http://www.bio.usyd.edu.au/Shinelab/.

Erratum

In the recently published article, "Analysis and Comparison of Three Capture Methods for the Eastern Hellbender (*Cryptobranchus alleganiensis alleganiensis*)," by Foster et al. (2008. vol. 39, pp. 181–186), an incorrect version of Table 2 appeared due to a printing error. The correct version of this paper is available as a pdf from the corresponding author, Amy McMillan (e-mail: mcmillam@buffalostate.edu).

SSAR Grants-in-Herpetology 2009
Call for Proposals

Proposals are now being accepted for the 2009 SSAR Grants-in-Herpetology program. This program is intended to provide financial support for deserving individuals or organizations involved in herpetological research, education, or conservation. Application deadline is 31 December 2008. Grant application details are available at:

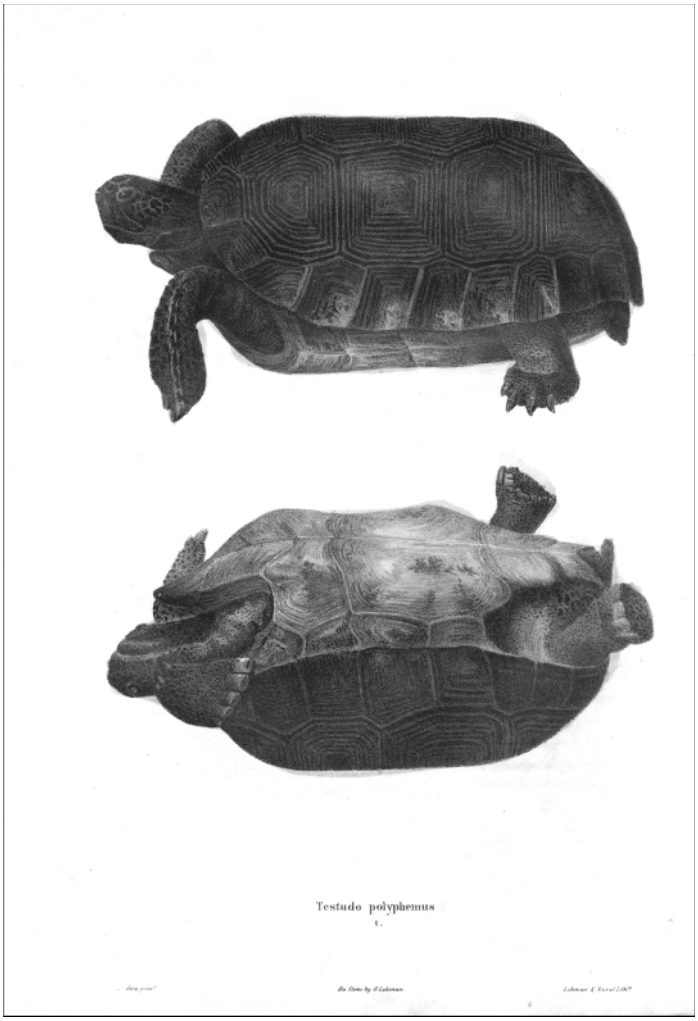
http://www.ssarherps.org/pages/GIH.php

ZOO VIEW

Updating the Bookshelves
Part I: Chelonians, Snakes, Amphibians

. . . interest in zoology is almost as much a physical part of the topography of reptile keepers' work as cleaning after animals. One of the ingredients that typifies a reptile keeper is nagging curiosity, and curiosity is something that cannot be taught. Answers to questions in zoology are tucked away in tons of technical literature. Popular sources of information— television, the warm glow of the Internet or entertaining articles for the lay audience with a generous dose of large color photos— are often too inadequate. A search for hard-core data requires a trip to the science section of a major library and hours of digging through hundreds of journals and volumes, in your own time. Unglamorous and tedious no doubt, but that is expected of professionals.

—Ken Kawata, 2005



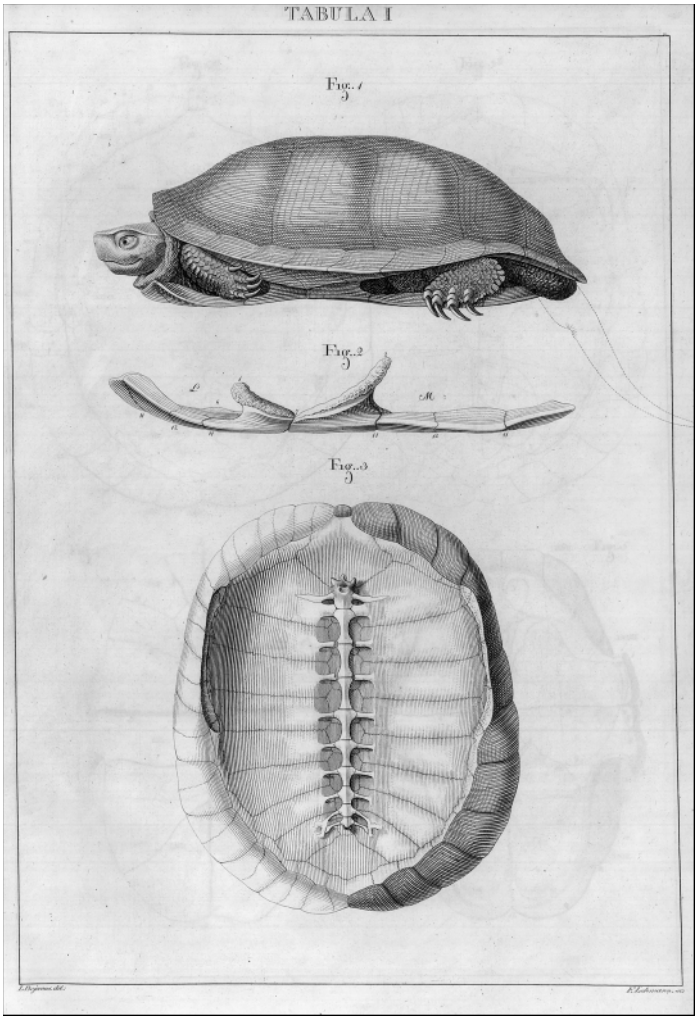
In William Shakespeare's *The Tempest* (Act 1, Scene 2), Prospero told us about the importance of a library when he said, "Me, poor man, my library was dukedom large enough." For anyone who dreams of building a working herpetological library, a number of books and papers have appeared in the past few years which will prove to be important references. I have selected some particularly useful ones below and paired them with historical images relevant to the publications. Part II will appear in the next issue.

Books and Papers on Chelonians

They select dry and sandy places, are generally found in troops, and are very abundant in pine barren countries. They are gentle in their habits, living entirely on vegetable substances. They are fond of the sweet potato, (Convolvulus batatas,) and at times do much injury to gardens, by destroying melons, as well as bulbous roots &c. &c. In the wild state they are represented as nocturnal animals, or as seeking their food by night: when domesticated, and I have kept many of them for years, they may be seen grazing at all hours of the day. When first placed in confinement, they chose the lowest part of the garden, where they could most easily burrow; this spot being once overflowed by salt water in a high spring tide, they migrated to the upper part, nearly eighty yards distant, and prepared anew their habitations. They seldom wandered far from their holes, and generally spent part of the day in their burrows. They delighted in the sun in mild weather, but could not support the intense heat of our summer noons; at those hours they retreated to their holes, or sought shelter from the scorching rays of the sun under the shade of broad-leaved plants. A tanyer, (Arum esculentum,) that grew near their holes, was a favourite haunt. They could not endure rain, and retreated hastily to their burrows or to other shelter at the coming on of a shower. As winter approached they confined themselves to the immediate neighborhood of their holes, and basked in the sunshine. As the cold increased, they retired to their burrows, where they became torpid; a few warm days, however, even in winter, would again restore them to life and activity. The adults are remarkably strong, sustaining and moving with a weight of two hundred pounds or more. The female is generally larger than the male, with the sternum convex; the sternum of the male is concave, especially on its posterior part. The eggs are larger than those of a pigeon, round with a hard calcareous shell: they are much esteemed as an article of food.

—John Edwards Holbrook on the Gopher Tortoise, 1842

Zoo workers have implemented a number of tortoise conservation initiatives, both in their institutions and in the wild. In a new book by Ray E. Ashton and Patricia S. Ashton called *The Natural History and Management of the Gopher Tortoise* Gopherus polyphemus *(Daudin)* (2008, Krieger, Malabar FL, ISBN 13:978-1-57524-162-3; ISBN 10:1-57524-162-5), the authors provide an excellent template as to how a thorough tortoise study should be designed and accomplished. They run the Ashton Biodiversity Research & Preservation Institute in Florida, where they are now comparing various savannah and semi-desert species from all over the world. In this book, the authors demonstrate the insights gained by studying tortoises for many years in the field versus short term observations. The forage chapters are extremely important in understanding tortoise dietary needs and behavior, especially the fact that the animals eat not only selective plants each season but also eat only certain parts of the plants. Various age classes chose almost entirely different plants. Secondly, the book goes into great detail about natural history, including seasonal patterns. Chapter 10 defines an often ignored element in a successful conservation undertaking—the complexity of not just knowing the natural history but also economics, community support, and the need for a long-term commitment. This book will likely set a benchmark as to what knowledge is necessary about tortoises and other amphibian and reptile species if we are going to manage them over time and beyond that, also enter into any form of *in situ* conservation.



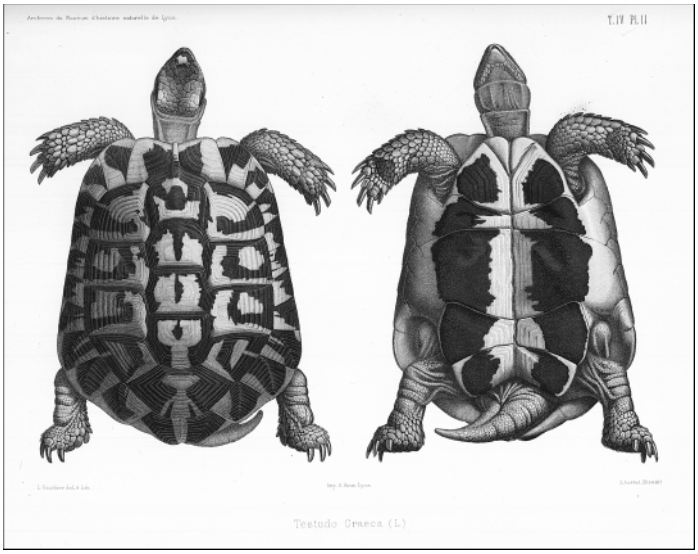
Drawing of Gopher Tortoise (*Testudo polyphemus*, now *Gopherus polyphemus*) in *North American herpetology; or, A description of the reptiles inhabiting the United States* by John Edwards Holbrook in 1842.

Imprint: Philadelphia, J. Dobson. [vol. 1, plate I]

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

In 1819–1821 Ludwig Heinrich Bojanus published *Anatome testudinis Europaeae. Vols. 1, 2.* This rare atlas was issued in an original edition of 80 copies, reprinted in 1902, and again in 1970 by SSAR. Written in Latin, the magnificent folio contains arguably the finest anatomical drawings of a turtle ever produced. The subject was the European Pond Turtle (*Testudo europaea*, now *Emys orbicularis*). There is no detailed text but extensive descriptions of the 30 numbered plates.

Exquisite rendition of anatomical features in the European Pond Turtle (*Testudo europaea*, now *Emys orbicularis*) in *Anatome testudinis Europaeae. Vols. 1, 2* by Ludwig Heinrich Bojanus in1819–1821.



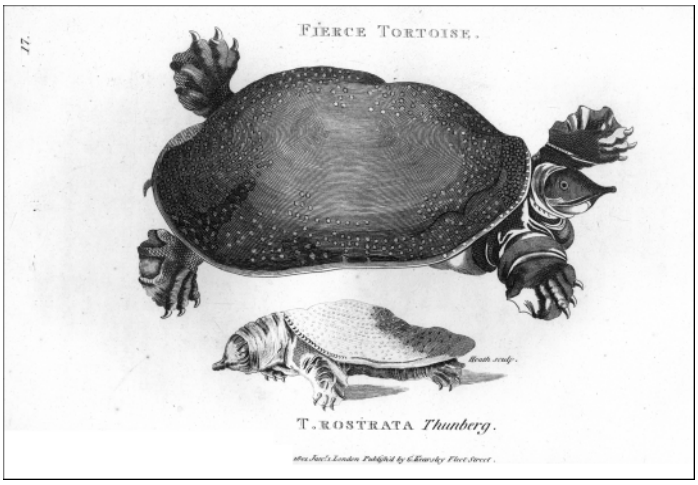
Imprint: Wilno (Vilna, Lithuania), published by the author.

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

Over a century later, J. Stuart Thomson studied the gross morphology of the Spur-Thighed Tortoise (*Testudo graeca*, now *T. g. graeca*) and Iberian Tortoise (*Testudo ibera*, now *T. g. ibera*). His contribution—published in *1932 Scientific Proceedings of the Royal Dublin Society* 20(28):359–462, plates 19–43—was called *The Anatomy of the Tortoise* and appeared after his death. This high-quality reprinted edition (2006, Bibliomania, Salt Lake City UT; ISBN 10:932871-10-1; ISBN 13:978-1-932871-10-4) includes an introduction by Gabe S. Bever and Christopher J. Bell covering Thomson's life, career, and importance to herpetology.

A new book called *Biology of Turtles*, edited by Jeanette Wyneken, Matthew H. Godfrey, and Vincent Bels, provides the first comprehensive review of the Testudinata in and out of the shell (2008, CRC Press, Boca Raton FL; ISBN 978-0-8493-3339-2). The book covers the turtle body plan in detail; physiological and ecological consequences, evolutionary novelties, and their importance. Some of the topics are of importance to veterinarians and pathologists: bone growth, bone strength and aging, cervical anatomy, skeletochronology, and cardiopulmonary structure. For the turtle keeper, the chapters on locomotion, feeding behavior, reproduction and mixed and uniform brood sex ratio strategy are important.

Chelonian Research Foundation: Anders G. J. Rhodin has been the driving force in creating this organization dedicated to research and conservation. The Foundation has published four Chelonian Research Monographs—one on Galápagos tortoises, another on the horrifying Asian turtle trade, and a third called *Biology and Conservation*



In his book, L. Lortet provided beautifully colored figures of the Spur-Thighed Tortoise and other Mediterranean tortoises.

Lortet, L. 1886. *Observations sur les tortues terrestres et paludines du bassin de la Mediterranée.*

Imprint: Lyon, Libraire de la Faculté de médecine et de la Faculté de droit.

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

George Shaw was the creator of the encyclopedic fourteen volume set called *General Zoology*. One important innovation by Shaw was the inclusion of common names, and his plates are labeled with common names throughout Volume 3 (part I). Here is plate 17 named Fierce Tortoise, now called Florida Softshell Turtle. The taxon was designated *Testudo Ferox* by Shaw and is now *Apalone ferox*. The name *Testudo rostrata*, now suppressed, may be a variation of the Florida Softshell Turtle.

Shaw, George. 1800–1826. *General zoology, or Systematic natural history . . .; with plates from the first authorities and most selected specimens, engraved principally by Mr. Heath.*

Imprint: London, Printed for G. Kearsley . . .

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

of Florida Turtles, edited by Peter A. Meylan. Each species account in this latter monograph treats the following subjects: species recognition and taxonomic history, distribution, habitat relations, growth and reproduction, population biology, interspecific interactions, threats, status, and conservation options and solutions.

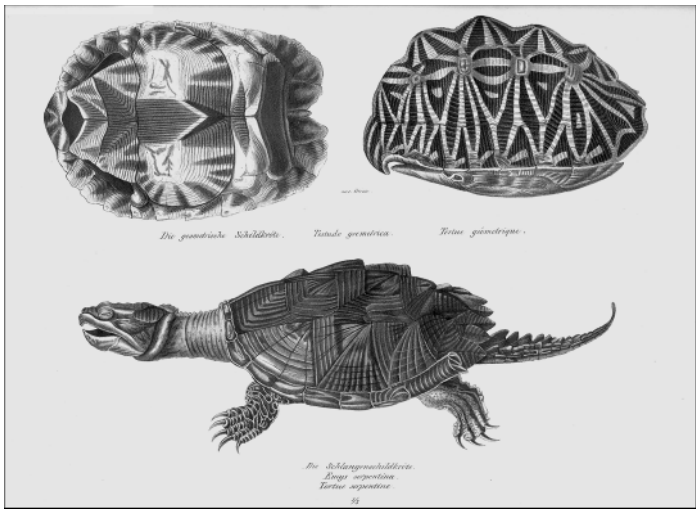
The fourth monograph is *Defining Turtle Diversity. Proceedings of a Workshop on Genetics, Ethics, and Taxonomy of Freshwater Turtles and Tortoises. Cambridge, Massachusetts, 8–12 August 2005.* This book was edited by H. Bradley Shaffer, Nancy N. FitzSimmons, Arthur Georges, and Rhodin and was published in 2007. There are several important chapters for captive managers: review of genetics studies during past 70 years, taxonomy, genetic considerations for captive breeding and translocation for conservation, internet resources, and an annotated list of modern terminal taxa, with comments on areas of instability and recent change.

Twice a year, the Foundation also prints a peer-reviewed journal of the highest quality—*Chelonian Conservation and Biology*—and a newsletter. In a recent issue, there is a review article by Dean Williams and Matthew Osentowski called, "Genetic considerations for the captive breeding of tortoises and freshwater turtles" (2007, 6[2]:302–313).

No zoo herpetologist should be without these publications. The journal is available by subscription from Chelonian Research Foundation, c/o Allen Press, P.O. Box 7065, Lawrence KS 66044 (phone: 785-843-1235, ext. 296; Fax: 785-843-1274; e-mail: crf@allenpress.com) or Chelonian Research Foundation, 168 Goodrich Street, Lunenburg MA 01462 (phone: 978-582-9668; Fax; 978-582-6279; e-mail: RhodinCRF@aol.com). Books may be ordered from the latter address.

THE FLESH OF THIS TURTLE IS USED FOR FOOD, LARGE NUMBERS OF ANIMALS BEING SOLD IN THE MARKETS OF OUR LARGE CITIES. THERE IS A STRONG ODOR OF MUSK, HOWEVER, WHICH DETRACTS FROM ITS VALUE, FOR IT COMMANDS ONLY A SMALL PRICE. USED IN A SOUP THE FLAVOR IS SAID TO BE EXCELLENT. IT IS CAPTURED MOSTLY WITH A BAITED HOOK WHICH IT TAKES MOST READILY, OFTEN TO THE EXASPERATION OF FISHERMEN. FORMERLY IN COUNTRY DISTRICTS IT WAS A COMMON CUSTOM TO KEEP A SNAPPING TURTLE IN A SWILL BARREL, WHERE IN THE COURSE OF TIME, IT GREW EXCEEDINGLY FAT, VERY TENDER, AND LOST MOST OF ITS MUSKY ODOR. IT WAS THEN KILLED AND EATEN. MR. S. W. DENTON OF WELLESLEY, MASS., TELLS ME HE KNEW OF A TURTLE KEPT UNDER SUCH CONDITIONS WHICH REACHED A WEIGHT OF EIGHTY-SIX POUNDS.

—HAROLD L. BABCOCK ON THE COMMON SNAPPING TURTLE, *THE TURTLES OF NEW ENGLAND*, 1919



The Biology of the Snapping Turtle (Chelydra serpentina) is the first broad biological treatment of the Common Snapping Turtle. Edited by Anthony C. Steyermark, Michael S. Finkler, and Ronald J. Brooks, this is the definitive reference for anyone working with or interested in this fascinating reptile. The book is published by The Johns Hopkins University Press (2008; The Johns Hopkins University Press, Baltimore MD; ISBN 13: 978-0-8018-8724-6 [hardcover]; ISBN 10:0-8018-9724-0 [hardcover]) and in it a number of prominent turtle biologists synthesize all that is known about this chelonian by providing an up-to-

In plate 89 called *Testudo* by Ernst Haeckel, the somewhat stylized taxa appear to be (left top, clockwise): leatherback and hawksbill sea turtles, mata mata, giant tortoise, snapping turtle, star tortoise, and snake-necked turtle. From *Kunstformen der Natur* (Art forms in nature) by Ernst Heinrich Philipp August Haeckel in 1899–1904.

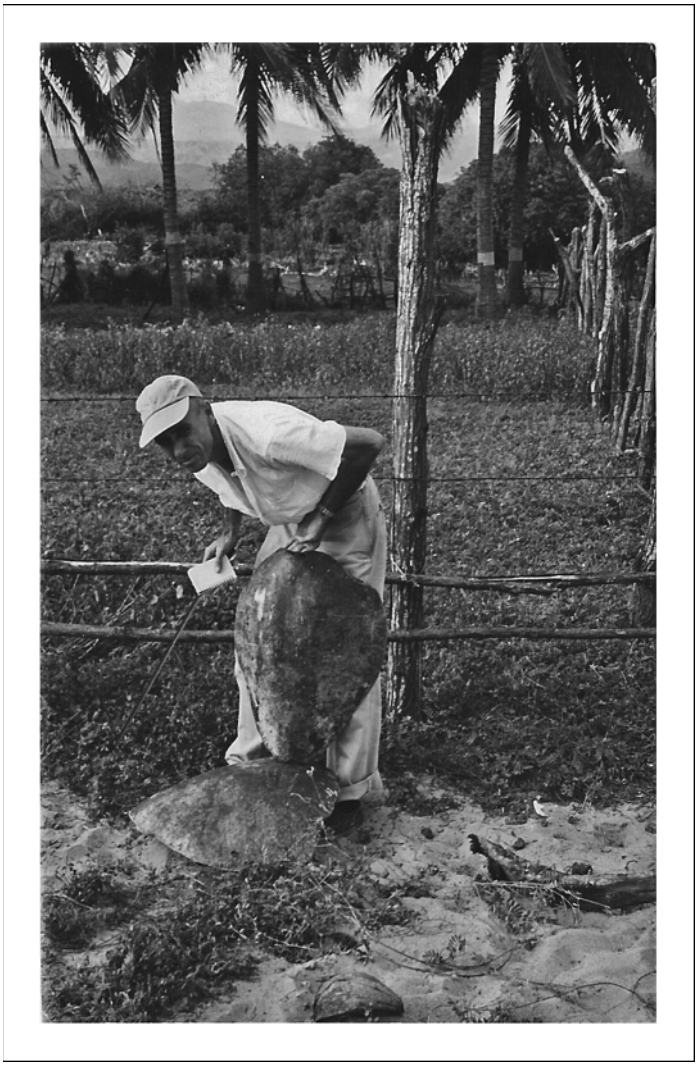
Imprint: Leipzig, Wien, Verlag des Bibliographischen Instituts.

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

Heinrich Rudolf Schinz was professor of natural history in Zürich. Many illustrations in his book include a variety of herps: developmental series of newts, lizards in naturalistic poses, caecilians, breeding behavior and development of anurans, complete drawings and skulls of caimans, gavials, and crocodiles, and a large series on snakes. Shown here is Common Snapping Turtle (bottom).

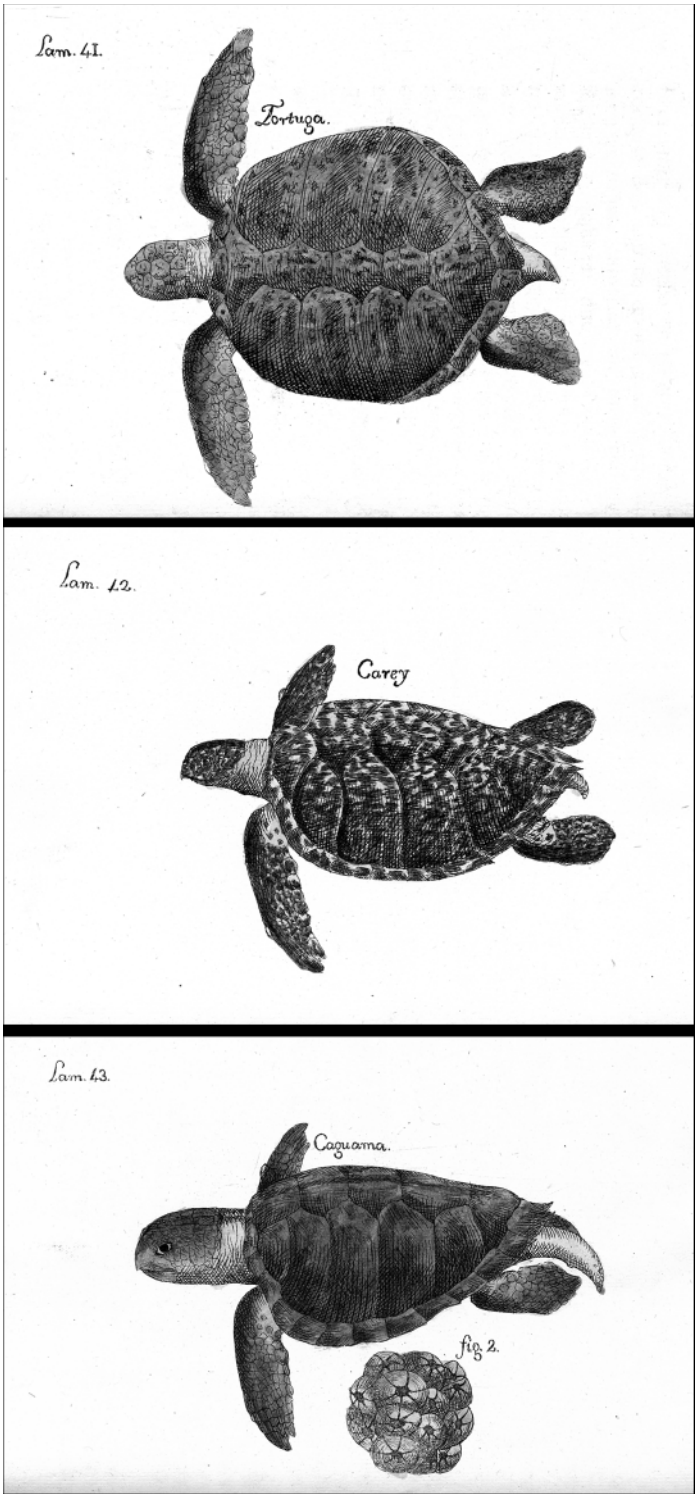
Schinz, Heinrich Rudolf. 1833. *Naturgeschichte und Abbildungen der Reptilien. Nach den neuesten Systemen zum gemeinnützigen Gebrauche entworfen und mit Berücksichtigung für den Unterricht der Jugend bearbeitet, / von H.R. Schinz. Nach der Natur und den vorzüglichsten Originalien gezeichnet, von K.J. Brodtmann.*

Imprint: Schaffhausen, in Brodtmanns lithographischer Anstalt.



Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

date comprehensive resource on the species' evolution, taxonomy, and systematics; physiology, energetics, and growth; and life history and ecology. There are several chapters which are particularly relevant to captive managers working with other chelonians from temperate climates: thermal ecology and feeding, ecology and physiology of overwintering, embryos and incubation period, sex determination, physiology and ecology of hatchlings, and geographic variation in life history traits.



The Johns Hopkins University Press published another important book on chelonians: *Turtles of the World* by Franck Bonin, Bernard Devaux, and Alain Dupré (2006, translated from French by Peter C. H. Pritchard, ISBN 0-8018-8496-9). Species accounts include distribution, description, natural history, and protection and all are accompanied by maps and excellent color photographs.

Archie Fairly Carr Jr.: One of our most prominent turtle biologists, the late Archie Carr, is the subject of two recent books. The first, by his former graduate student Peter C. H. Pritchard, is called *Tales from the Thébaïde. Reflections of a Turtleman* (2007, Krieger, Malabar, Florida; ISBN 1-57524-277-X). In the first chapter titled "The master turtler," Pritchard provides an overview of Carr's life, details his many contributions to science, and presents a moving account of the time he spent with Carr.

The second book is *The Man Who Saved Sea Turtles. Archie Carr and the Origins of Conservation Biology* by Frederick Rowe Davis (2007, Oxford University Press, Oxford, New York; ISBN 978-0-19-531077-1). Carr began writing about sea turtles in 1942 and was passionate about

Photograph of Archie Carr with turtle shells was taken at Pie de la Cuesta, Guerrero, Mexico in 1951 by Charles M. Bogert. Credit: courtesy of Kraig Adler.

Archie Carr studied Green (plate 41), Hawksbill (plate 42), and Loggerhead (plate 43) Sea Turtles, beautifully pictured in *Descripcion de diferentes piezas de historia natural las mas del ramo maritimo : representadas en setenta y cinco laminas / su autor don Antonio Parra* by Antonio Parra (Parra y Callado) in 1787.

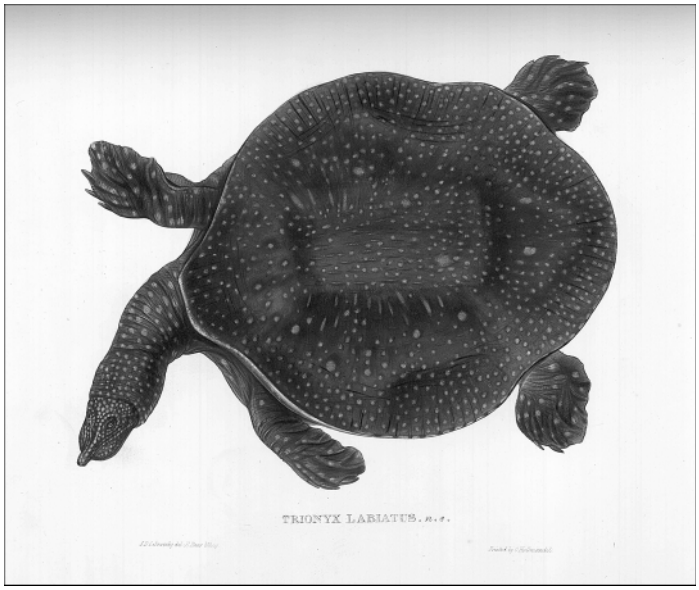
their protection throughout his life. He was a gifted writer and author of many important books: *A Contribution to the Herpetology of Florida* (1940); *Handbook of Turtles* (1952); *High Jungles and Low* (1953); *The Windward Road* (1956); *The Reptiles* (1963); *Ulendo* (1964); *Africa* (1964); *So Excellent a Fische* (1967); and *A Naturalist in Florida* (1994). When Carr was asked why he liked turtles by a newspaper reporter a month before he died in 1987, he replied, "I just liked the looks on their faces. There is an old, wise, sort of durable aboriginal look about turtles that fascinates people." (in Pritchard, 2007:10).

Fines- Mundi Verlag has reprinted three classic works on chelonians of the highest quality. I have compared these reprinted plates with the originals and there is no essentially no difference between the two.

The first is by Johann David Schöpf, a German medical doctor, zoologist and botanist whose only herpetological contribution was this atlas written in Latin and German —*Ioannis Davidis Schoepff Historia testudinum iconibus illustrata* and *Naturgeschichte der Schildkröten*. Schöpf died at age 48 before his contribution was completed. Shown here is the Mata Mata.

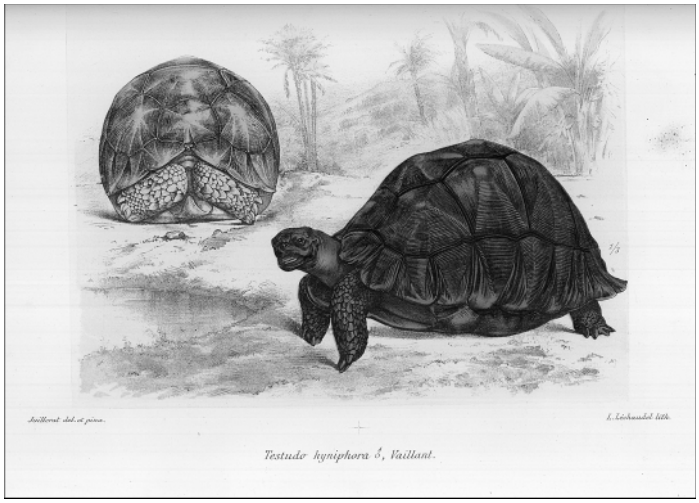


Drawing of Mata Mata called *Testudo fimbriata* (now *Chelus fimbriatus*) in *Ioannis Davidis Schoepff Historia testudinum iconibus illustrata* by Johann David Schöpf in 1792 [–1801].

Imprint: Erlangae [Erlangen], Sumtibus Ioannis Iacobi Palm.

German edition *Naturgeschichte der Schildkröten* (Erlangen, J. J. Palm, 1792 [–1801]).

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.



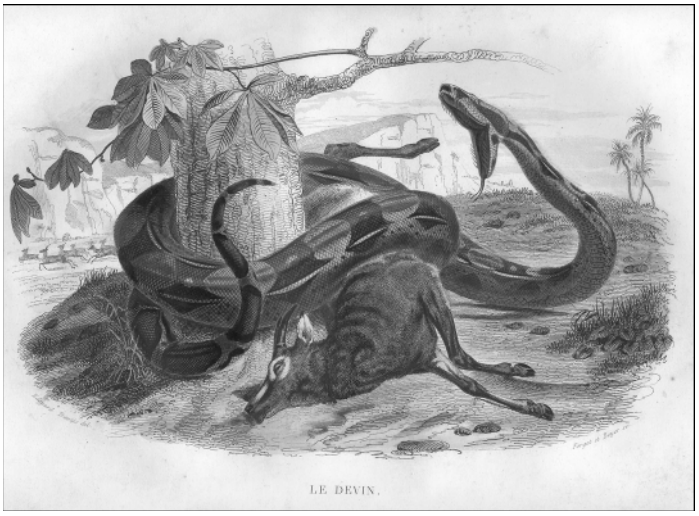
Artist James de Carle Sowerby and lithographer Edward Lear mostly used living specimens as models to create 41 extraordinary plates which were first published in Thomas Bell's folio work *A Monograph of the Testudinata* in 1832–36. Forty years later, the plates were reissued, along with additional ones, and a short text by John Edward Gray from the British Museum of Natural History called *Tortoises, Terrapins, and Turtles Drawn from Life*, by James de Carle Sowerby and Edward Lear. One of the most magnificent pictures in the Bell volume is the Nile Softshell Turtle pictured here.

Nile Softshell Turtle (*Trionyx labiatus*, now *Trionyx triunguis*) from Thomas Bell's *A Monograph of the Testudinata*. London : s.n., in 1832–36.

Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

The Menagerie of the Museum of Natural History in Paris was created in 1793 and was the first of the national menageries. It has a rich history as a center for experimental zoology. Many French herpetologists used

Due to human impact, two of the rarest species on the planet are nearly extinct: Madagascan Big-Headed Turtle (*Erymnochelys madagascariensis*) and Northern Madagascan Spur Tortoise (*Geochelone* (*Astrochelys*) *yniphora*) pictured here from *Histoire physique, naturelle, et politique de Madagascar*.



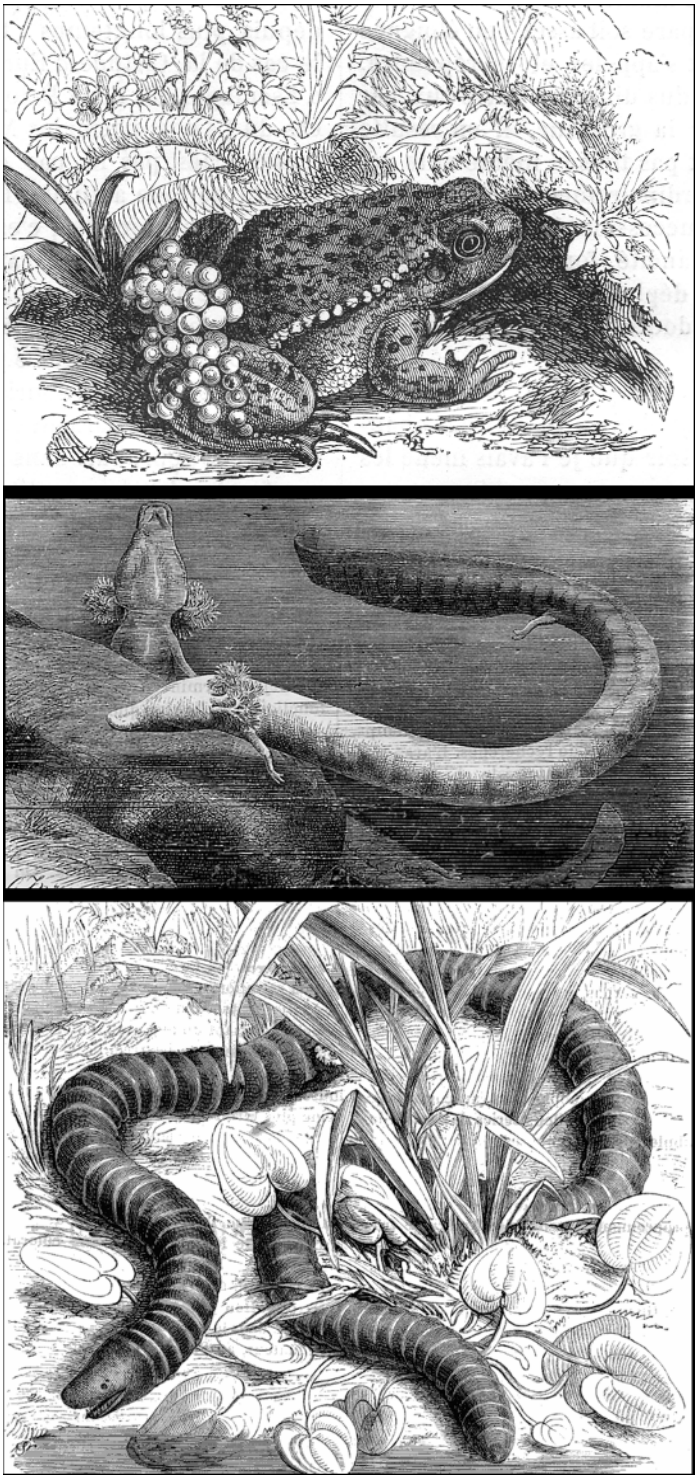
Credit: Collections of Ernst Mayr Library, Museum of Comparative Zoology, Harvard University.

the Menagerie to observe living animals. In addition to his regular duties in the museum, Léon Vaillant was in charge of the reptile menagerie and aquarium. He published *Muséum d'histoire naturelle Guide à la ménagerie des Reptiles. Laboratoire d'Herpétologie, Paris* in 1898. In 1910, Vaillant and Guillaume Grandidier published *Histoire physique, naturelle, et politique de Madagascar* publiée *par Alfred et Guillaume Grandidier. Volume XVII Histoire Naturelle des Reptiles*, presenting 27 of the most exquisite herpetological plates ever produced.

All of these superb facsimiles (and other rare herpetological tomes from the past) are available from Fines- Mundi GmbH, Die Lach 4, 66121 Saarbrücken, Germany; info@fines-mundi.de; www.fines-mundi.de.

Snakes

In a comprehensive and lavishly illustrated book called *Biology of the Boas and Pythons* (2007, Eagle Mountain Publishing, Eagle Mountain UT; ISBN 978-0-9720154-3-4), editors Robert W. Henderson and Robert Powell have solicited chapters covering a wealth of topics from many experts: ecology, natural history, and evolution; behavior; physiology, neurology, and reproductive biology; and conservation. One of the most interesting sections deals with the problems caused by introduced populations, now reproducing, of Boa Constrictors (*Boa constrictor*) and Burmese Pythons (*Python molurus bivittatus*) in southern Florida. Recently, there have been a number of sensational newspaper stories in response to a press release issued in mid-February 2008 by the United States Geological Survey (USGS) about invasive alien pythons in Florida and the possibility of this taxon extending its range to other parts of the United States. Two of the book's authors, David G. Barker and Tracy M. Barker, were stimulated to write two subsequent articles in response: "Comments on a flawed herpetological paper and an improper and damaging news release from a government agency." (Bull. Chicago Herpetol. Soc. 43(3):45–47) and "Review: *An ecological risk assessment of nonnative boas and pythons as potentially invasive species in the United States* by Robert N. Reed. 2005. Risk Analysis 25(3):753–766." (Bull. Chicago Herpetol. Soc. 43(4):63–67).



Boa Constrictor (*Boa constrictor*) from *Histoire naturelle de Lacépède, comprenant les cétacés, les quadrupèdes ovipares, les serpents et les poissons* by Bernard Germain Etienne de La Ville sur Illon La Cépède (Count de Lacepède**)** in 1860.

Imprint: Paris, Furne, 1860.

Amphibians

For the zoo professional working with living amphibians, Kentwood D. Wells has written a splendid book detailing their biology—*The Ecology and Behavior of Amphibians* (2007, The University of Chicago Press, London, Chicago; ISBN 13:978-0-226-89334-1 [cloth], ISBN 13:978-

In his book, Kentwood Wells describes the diversity of amphibians including the Midwife Toad (*Alytes obstetricans*), European Olm (*Proteus anguinus*), and Ringed Caecilian (*Siphonops annulatus*). These beautiful plates are in A. E. Brehm's *Les Merveilles de la Nature. Les Reptiles et les Batraciens* (Librairie J.-B. Baillière et Fils, Paris, 1883).

0-226-89335-8 [paper]). Topics explained in detail include phylogeny, classification, and morphological evolution; temperature relations, respiration, metabolism and energetics; movements and orientation; anuran vocal communication; mating systems and sexual selection in anurans; communication and social behavior of urodeles and caecilians; natural history of amphibian reproduction; parental care; ecology and behavior of amphibian larvae; complex life cycles and ecology of amphibian metamorphosis; predation upon amphibians; ecology of amphibian communities; and conservation. Wells describes the plight of amphibians in the last chapter and his words reflect future challenges for the zoo community—"Clearly much more needs to be done. We cannot save all species of amphibians, and we are going to lose some pretty spectacular products of evolution, particularly in the tropics. Many frogs with strange and unusual breeding habits, especially those adapted to the interiors of tropical forests, are likely to be lost, as are some species equipped with arsenals of chemical weapons in their skins, some of which might be used to fight human diseases in the future. In many cases, we may lose species of amphibians before we even know they exist. Yet there is some hope."

International Zoo Yearbook: In volume 42 (2008), there is a special section on amphibian conservation covering many topics—Conservation (role of zoos and aquariums, "Amphibian Conservation Action Plan," "Amphibian Ark" and "2008 Year of the Frog Campaign," status of Taipei Frog *Rana taipehensis* [=*Hylarana*], status of Farmland Green Tree Frog *Rhacophorus arvalis* in Taiwan, Axolotyl *Ambysoma mexicanum* at Lake Xochimilco, Mexico, Afrotropical anurans in zoos, South Asian, South African, Panamanian, and Colombian amphibians); Captive management (disease, water quality, automatic waste-water disinfection system); Behavior and reproduction (Kingsbury's Rocket Frog *Allobates kingsburyi*, Colombian Magdalena River Poison-Dart Frog *Dendrobates truncatus*, Rocket Frog *Hyloxalus toachi*, Romer's Tree Frog *Chirixalus romeri* [=*Chiromantis*]). Although disquieting, Tim Halliday's article on why amphibians are important is an excellent review of accelerating human effects threatening the global ecosystem.

Try to find a copy of a spectacular picture book entitled *Oo-sansho-uo (Giant Salamander)* showing the life history of the Japanese Giant Salamander (*Andrias japonicus*) throughout the four seasons in the wild by Ryu Uchiyama, published by Biburosu, Tokyo, 10 November 2003 (ISBN4-8352-1498-6). The Japanese text is minimal but the photos are eloquent.

Japanese Giant Salamander (*Andrias japonicus*) from a lithograph drawn from life by the Dutch natural history artist, A. Saagmans Mulder (from Philipp Franz de Siebold's *Fauna Japonica*, Reptilia part 3, Leiden, 1838). Credit: provided by Kraig Adler.

In 2006, Darrel Frost and 18 coauthors published *The Amphibian Tree of Life* (Bull. Amer. Mus. Nat. Hist. No. 297:1–370); the purpose was to construct a new taxonomy of living amphibians to correct the deficiencies of the old one. Such a massive undertaking was bound to generate criticism; for example—Wiens (2007, book review: the amphibian tree of life, Q. Rev. Biol. 82:52–55). In a subsequent paper titled "Is *The Amphibian Tree of Life* really fatally flawed?" Frost et al. (2008, Cladistics 24:385–395) responded to the criticisms elucidated by Wiens. I mention these publications here, not to evaluate the evidence but rather to alert zoo biologists that change is coming. Are you ready to modify the scientific name on your American Bullfrog exhibit from *Rana catesbeiana* to *Lithobates catesbeianus*?

Herps

In 2005, The University of Chicago Press published two books which covered reptiles as well as amphibians. The first, by Marty Crump, was called *Headless Males Make Great Lovers & Other Unusual Natural Histories* (ISBN 0-226-12199-2 [cloth], ISBN 13: 978-0-226-12202-1 [paper]), filled with charming descriptions of the behaviors of a host of creatures ranging from sponges to mammals. There is plenty here to entice the zoo herpetologist: unusual parental behaviors of poison dart and rocket frogs, marsupial frogs, gastric brooding frog, gladiator frogs, and other anurans; salamander courtship; snake and turtle mating and the production of eggs; snakebites and venom; American Alligator parental care, and many others.

The other book is the definitive treatment of the state of herpetological investigation in the tropics and it is fitting that the remarkable achievements of our colleague Jay M. Savage were highlighted and celebrated throughout this volume. Edited by Maureen A. Donnelly, Brian I. Crother, Craig Guyer, Marvalee H. Wake, and Mary E. White, the book called *Ecology & Evolution in the Tropics. A Herpetological Perspective* (ISBN 0-226-15657-5 [cloth]; ISBN 0-226-15658-3 [paper]), encompasses two parts—evolution and biogeography; ecology, biogeography, and faunal studies. Twenty-eight contributors, known for their expertise in tropical biology, authored eighteen chapters. Of the 32 Savage students listed in Altig (2007), sixteen were involved in the production of this book—S.-H. Chen, B. I. Crother, M. A. Donnelly, S. B. Emerson, C. Guyer, W. R. Heyer, A. G. Kluge, K. L. Lips, R. W. McDiarmid, K. E. Nicholson, N. J. Scott Jr, J. B. Slowinski, D. B. Wake, M. H. Wake, S. D. Werman, and M. E. White. In the foreword, Luis D. Gómez summarizes the Savage impact beautifully, "After his monumental opus, *The Amphibians and Reptiles of Costa Rica* (2002), this low-profile humble man with the textbook diastema and his perennial jovial disposition, precipitates a deluxe array of authors who celebrate his accomplishments by giving us, and several generations to come, the blue-print of what is known of the tropical herpetofauna and what would be desirable to know in the near future. That is Savage, the engine, at his best."

For many years, the Malay Peninsula has been a focal point for herpetological investigations (e.g., Berry 1975; Boulenger 1912; Butler 1904; Cantor 1847; Chan-ard et al. 1999; Das and Norsham 2007; Kloss 1915, 1921; Lim and Das 1999; Denzer and Manthey 1991; Flower 1896, 1899; Manthey and Grossmann 1997; Smith 1930; Tweedie 1983; Wood et al. 2008b) and the complex biogeographical history of its fauna has only recently begun to emerge (Inger 1999; Pauwels et al. 2003). It is one of the world's longest peninsulas, extending roughly 1660 km from Samut Songkhram, Thailand in the north, southward to the southern coast of Singapore. Its topography is sculpted by a discontinous series of mountain ranges that begin in the highlands of central Indochina and run nearly its entire length (Fig. 1). In Peninsular Malaysia (= West Malaysia), these ranges trifurcate

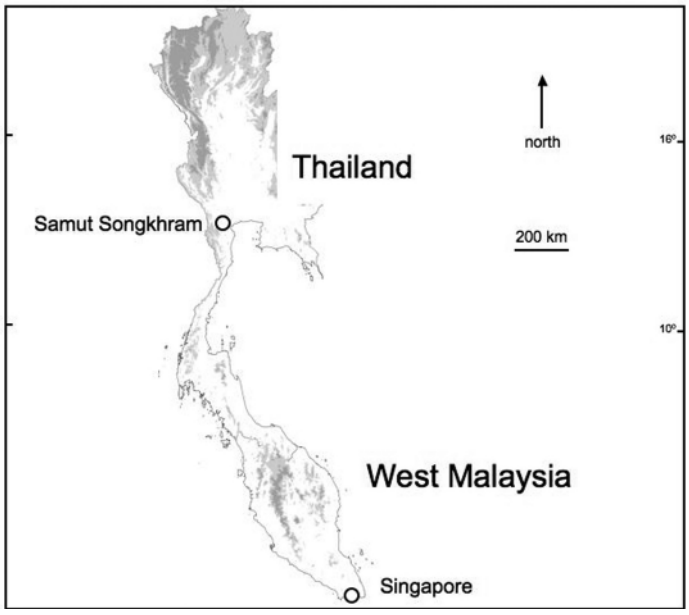

FIG. 1. Location map showing the extent of the Malay Peninsula.

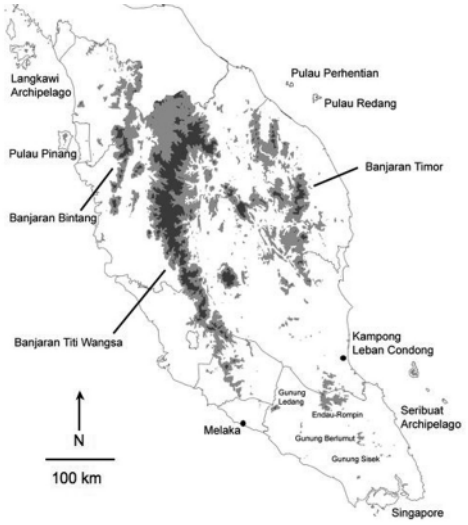

FIG. 2. Map of Peninsular Malaysia showing its three major mountain ranges, its major archipelagos, and the extent of and topographical features of southern West Malaysia (SPM) discussed in the text.

in the north, fan out, and extend southward as the expansive and fragmented Banajaran Timor in the east, the Banjaran Bintang in the west, and the longest and centrally positioned Banjaran Titi Wangsa (Fig. 2). Paralleling these mountain systems are a series of shallow-water archipelagos and islands whose geological origins are tied to those of the adjacent peninsular mountains. Despite the growing tourism industry generated by the aesthetic appeal of these insular systems, their mountainous interiors for the most part, remain covered with relatively unexplored, pristine rainforest. The Langkawi Archipelago and Pulau Pinang are the most prominent island groups along the west coast of Peninsular Malaysia, whereas Pulau Rendang, Pulau Perhentian and several smaller islands scattered in their general vicinity dominate the waters off the northeast coast (Fig. 2). Off the southeast coast of Peninsular Malaysia lies the extensive Seribuat Archipelago (commonly referred to as the Tioman Islands) with 62 islands extending along the northern and southern shores of the states of Johor and Pahang, respectively (Fig. 2).

It has been known for many years that the mountain ranges of Peninsular Malaysia are regions of high herpetological diversity and endemism (e.g., Boulenger 1900; Das et al. 2004; Das and Norsham 2003; Dring 1979; Grandison 1972; L. L. Grismer et al. 2004a; Grismer 2006b, 2007a, 2008a; Hallerman and McGuire 2001; Leong and Lim 2003; Lim et al. 2002; Matsui and Ibrahim 2006; McLeod and Norhyati 2007; Norsham and Lim 2002; Sanders et al. 2004; Smedley 1931; Smith 1922, 1935; Vogel et al. 2004; Wood et al. 2008a). Recent studies are now beginning to reveal that an equally, if not more impressive degree of diversity and endemism occurs in the offshore archipelagos. This becomes germane as the results from ongoing expeditions on Pulau Langkawi (Grismer 2008b; Grismer et al. 2006b) and especially in the Seribuat Archipelago (see Grismer 2006c; Grismer et al. 2006a and references therein) continue to emerge and consistently report new island records and species previously unknown to science. With the exception of Singapore, which has a rich history of herpetological research (e.g., Leong and Chou 1997, 1999; Leong et al. 1996; Lim 1989a,b; Lim and

Chou 1990; Lim and Lim 1992; Lim and Yang 1991; Sworder 1922, 1924a,b, 1925), herpetological studies in the lowlands of southern Peninsular Malaysia—roughly that area from Endau-Rompin National Park (Endau-Rompin) in southern Pahang and northern Johor, southward throughout the state of Johor (Fig. 2)—have been few (Sworder 1925). Recent work, however, focused in Endau-Rompin and surrounding areas has significantly increased the herpetofaunal diversity of southern Peninsular Malaysia (SPM) in both the number of newly reported species and the discovery of new species (Bhaarathyraja 2006; Daicus and Hashim 2004; Grismer 2006a, 2007b; Grismer and Leong 2005; Grismer et al. 2007b; Juliana 2001; Kiew 1987; Lim, 1989c; Norhayati and Dionysius 2004; Norhayati et al., 2004; Wood et al. 2008b). The same is true for the Seribuat Archipelago where recent studies have contributed to a tremendous increase in this region's diversity and endemism (see Grismer 2006c; Grismer et al. 2006a and references therein). The intent of this essay is to 1) highlight the diversity and high levels of endemism of the herpetofauna of SPM; 2) establish the importance of this region in efforts to conserve tropical biodiversity; 3) indicate the major current threats to its herpetofauna; and 4) to underscore the urgent, ongoing need for field-based, systematic research in this understudied region of the Malay Peninsula.

Southern Peninsular Malaysia

As delineated here, SPM occupies approximately 1620 km^2. It extends from the city of Melaka, Melaka (2.1991667°N, 102.2544444°E) on the west coast to Kampong Leban Condong, Pahang (2.8719444°N, 103.4341667°E) on the east coast, and southward through Singapore (1.2513889°N, 103.8256667°E; Fig. 2). In Peninsular Malaysia, this is roughly the entire state of Johor and the southern section of the state of Pahang and includes all low-lying areas below 150 m as well as the mountainous areas encompassing Gunung Ledang (1276 m) in northeastern Johor; Endau-Rompin in southern Pahang and northern Johor, reaching 1036 m at Gunung Besar; and a system of mountains in central Johor dominated by Gunung Berlumut (1010 m) in the north and extending southward ca. 57 km to Bukit Sisek (430 m) in the south (Fig. 2). Also, included in this region are the 62 islands of the Seribuat Archipelago lying off the east coast of SPM (Fig. 2) that extend ca. 100 km from Pulau Cebeh off the coast of southern Pahang, southward to Pulau Tokong Yu off the coast of central Johor.

Originally, continental SPM was an expansive region of lowland rainforest punctuated by isolated mountains and mountain ranges. Currently, the majority (~65%) of the lowland rainforest has been converted into agricultural fields supporting rubber tree and oil palm plantations. This is especially true of the western half and southern third. Continuous lowland rainforest remains in the northeastern third of continental SPM as well as a few scattered patches in the west. Peat swampforests are found in isolated patches in the east and west and freshwater swampforests dominate the southeastern corner. Fringing the coastal areas are isolated stands of mangrove swamps, which are particularly noteworthy in the south. Intact montane forest exists in all areas above 300 m, most notably in Endau-Rompin, Johor, the Gunung Berlumut system, and Gunung Ledang.

The environmental diversity of the Seribuat Archipelago off the east coast of SPM is unparalleled by any other island groups of Peninsular Malaysia (Grismer 2006c, 2008b; J. L. Grismer et al. 2004; L. L. Grismer et al. 2006b; Tamblyn 2005). This is paramount to the generation and maintenance of its herpetofaunal diversity and its broad array of adaptive types (Grismer et al. 2006a). The large islands (> 4.0 km^2) such as Aur, Babi Besar, Pemanggil, Tinggi, Tioman, and Sibu generally maintain extensive tracts of primary dipterocarp forest (Fig. 3). The largest of these islands, Tioman and Tinggi, also maintain significant sources of permanent fresh water in the form of streams, which harbor aquatic and riparian species not found on the other islands. Pulau Tioman even has a small river system, S. Mentawak (Fig. 4) which serves as the only locality in the archipelago for the frog *Rana picturata*. Conversely, many of the very small islands (< 0.03 km^2) such as the "Tokongs" are little more than wind-blown, arid, rocky outcrops rising precipitously out of the ocean, supporting only grasses and low-growing shrubs (Fig. 5). But here too, potentially endemic species have been found which occur nowhere else in the archipelago (Grismer 2006a, b). The intermediate-sized islands may be barren (P. Layak), forested (P. Babi Hujong), or combinations of both such as in the Seribuat group (sensu Grismer et al. 2006a) and may or may not support ephemeral bodies of fresh water. Many of the islands in the archipelago, both large and small, are fringed with broad stands of mangroves.

The Herpetofauna

Like other regions within tropical, megadiversity hotspots (Myers et al. 2000), the flora and fauna of SPM are extremely rich (Shaharuddin et al. 2004; Sham 1998; Yong 1998), and in regards to the herpetofauna, the documented diversity is experiencing a sharp increase as a result of recent and ongoing field work (Table 1). Focused efforts in continental SPM since 2005 have led to the discovery of at least four species previously unknown to science, the re-discovery of an extremely rare species (Daicus and Hashim 2004; Grismer 2006a, 2007b, Grismer and Leong 2005; Grismer et al. 2007b; Wood et al. 2008b), and an increase in the diversity of the herpetofauna of Endau-Rompin by at least 33% (Wood et al. 2008b). This trend has been particularly evident (not to mention surprising) in the Seribuat Archipelago where, since 2001, 186 new insular species records were added (Grismer 2006c; Grismer et al. 2006a and references therein) and at least 13 new species were discovered and described (Table 1), increasing the total diversity of the archipelago by 60% since the major contributions of Lim and Lim (1999) and Hien et al. (2001). Such dramatic increases in diversity over such a relatively short period clearly indicate that these regions remain significantly understudied and their actual diversity has yet to be realized.

To date, five families of frogs representing at least 53 species, and one family of caecilian representing an unknown number of species (see below), are confirmed for SPM (Berry 1975; Grismer 2006c; Wood et al. 2008b; Table 1). Not including caecilians, this represents ca. 59% of all the species of amphibians known from Peninsular Malaysia (based on Das and Norsham 2007) in less than 14% of the total area of the country. The reptilian fauna is even more diverse with three families of terrestrial and

FIG. 3. Pulau Tioman, Pahang; a) dipterocarp forest canopy, b) understory vegetation, and c) rocky streamside habitat.

freshwater turtles representing 11 species, eight families of lizards representing 60 species, eight families of non-marine snakes representing 90 species, and one crocodilian species (Table 1). Collectively, this represents ca. 65% of the reptilian fauna of Peninsular Malaysia (based on Das and Norsham 2007).

Perhaps of greater importance, however, is the role SPM plays in harboring endemic species. Since the description of *Cyrtodactylus sworderi* (Smith 1925), two new species of frogs (Grismer 2006a; Grismer 2007b) and a new species of lizard (Grismer and Leong 2005) have been described from continental SPM. Additionally, there is another species of snake (*Macrocalamus* sp.) in the

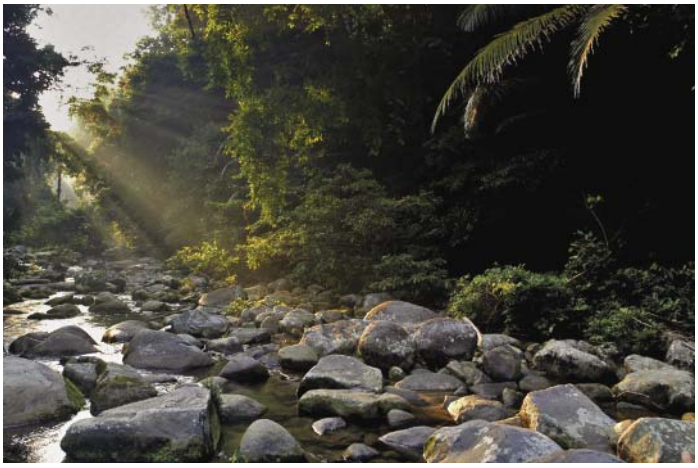

FIG. 4. Sungai Mentawak, Pulau Tioman, Pahang.

process of being described. This recent increase in the level of endemism has been particularly noteworthy in the Seribuat Archipleago. Prior to 1967, only one endemic species, *Ansonia tiomanica* Henderson 1966 (Hendrickson 1966a,b) was known and occurred only on Pulau Tioman. From 1999–2006, one new caecilian, one new frog, 10 new lizards, and four new snakes were described (see Grismer 2006c and references therein; Table 1), increasing the level of endemism by a factor of 16.

ENDEMIC SPECIES OF SOUTHERN PENINSULAR MALAYSIA

Apoda (Caecilians)

Ichthyophiidae.—Most recently *Ichthyophis monchrous* Bleeker 1858, *I. glutinosus* (Linneaus, 1758), *I. singaporensis* Taylor 1960, and *I. paucisulcus* Taylor 1960 have been reported from SPM (Boulenger 1912; Daicus and Hashim 2004; Kiew 1987; Lim and Lim 1992). However, there are several striped putative species known from the Malay Peninsula (Berry 1975; Manthey and Grossmann 1997, Lim and Lim 1992; Taylor 1968) and all have an extremely conserved morphology, making it difficult to distinguish one species from another, resulting in a confusing and unstable taxonomy (Gower et al. 2002). Until the completion of ongoing molecular analyses (D. Gower, pers. comm. 2006), assignment of any population to species cannot be done with confidence.

FIG. 5. Pulau Tokong Burong, Johor.

Anura

Bufonidae.—There are at least 10 species of bufonids confirmed for SPM, of which three are endemic (Table 1). *Ansonia tiomanica* Hendrickson 1966 (Fig. 6) is known only from Pulau Tioman in the Seribuat Archipelago. It was originally reported to occur at elevations above 800 m (Hendrickson 1966a) in close association with large boulders not associated with streamside habitat. Another population was subsequently discovered along a stream course below 300 m (Grismer et al. 2006a). This population, however, was extirpated with the modification of the stream to form a water catchment basin in 2004. *Ansonia endauensis* Grismer 2006 (Fig. 7) was recently discovered and described from Endau-Rompin, Johor. Specimens were found perched on leaves and rocks at the water's edge in some of the small tributaries of the Sungai Endau in the Peta region. *Ingerophrynus gollum* Grismer 2007 (Fig. 8) is a small toad also recently discovered and described from the Peta region of Endau-Rompin. Three males were heard calling from a small, swampy area cloaked in thick vegetation beneath a closed-canopy in lowland dipterocarp forest.

Megophryidae.—There at least four species of megophryids confirmed for SPM, one of which, *Leptolalax kajagensis* Grismer, Grismer, and Youmans, 2004 (Fig. 9), is endemic to Pulau Tioman (Table 1). L. L. Grismer et al. (2004b) reported this species to occur above 400 m on Gunung Kajang. On steep slopes at higher elevations where streams do not occur, *L. kajangensis* breeds in subterranean watercourses found beneath giant granite boulders. Tadpoles here develop in complete darkness and lack integumentary pigments (Grismer 2006c; Fig. 9).

Squamata (Lizards)

Dibamidae.—There is only one dibamid confirmed for SPM, *Dibamus tiomanensis* Diaz, Leong, Grismer, and Norsham 2004 (Fig. 10), which is known only from Tulai and Tioman islands. Like most other dibamids, *D. tiomanensis* occurs beneath surface debris, leaf litter, and within loose soils (Grismer 2006c). Given the secretive, fossorial nature of dibamids in general and their widespread, fragmented occurrence throughout Southeast Asia (see Das and Lim 2005 for review), it would be unlikely for *Dibamus* not to occur in continental SPM.

Gekkonidae.—Gekkonids have been very successful in SPM with at least 22 confirmed species of which eight from the genera *Cnemaspis* Strauch, 1887 and *Cyrtodactylus* Gray, 1827 are endemic (Table 1). *Cnemaspis* is represented by four species in SPM, of which three are endemic to the Seribuat Archipelago. *Cnemaspis baueri* Das and Grismer, 2003 (Fig. 11) occurs only on Pulau Aur. Like many other species of *Cnemaspis*, it is scansorial but restricted to the shaded surfaces of large boulders and within cave-like situations formed by piles of large boulders (Grismer 2006c). *Cnemaspis limi* Das and Grismer, 2003 (Fig. 12) is known only from Tulai and Tioman islands and has a lifestyle very similar to that of *C. baueri*. *Cnemaspis pemanggilensis* Grismer and Das, 2006 (Fig. 13) is endemic to Pulau Pemanggil. Its lifestyle is generally more restrictive than that of *C. limi* and *C. baueri* in that it rarely leaves the shelter of its cave-like habitats.

The genus *Cyrtodactylus* is represented in SPM by eight species, of which five are endemic. Three of these, *C. aurensis* Grismer 2005, *C. seribuatensis* Youmans and Grismer, 2005, and *C. tiomanensis* Das and Lim, 2000 are restricted to the Seribuat Archipelago, whereas *C. semenanjungensis* Grismer and Leong, 2005 and *C. sworderi* (Smith, 1925), are known only from the state of Johor. *Cyrtodactylus aurensis* (Fig. 14) is endemic to Pulau Aur and has a relatively restricted lifestyle in that it primarily occurs on large boulders and trees situated beneath closely overhanging vegetation (Grismer 2005, 2006c). *Cyrtodactylus seribuatensis* (Fig. 15) has the most extreme life style of any of Malaysia's gekkonids. On the seven small islands on which it is found (Youmans and Grismer 2005), it is restricted to the hypersaline intertidal zone where it takes refuge and forages for food (Grismer 2006c). *Cyrtodactylus tiomanensis* (Fig. 16) is endemic to Pulau Tioman and is more typical in *Cyrtodactylus* behavior, being common on the trunks of trees and large boulders. *Cyrtodactylus semenanjungensis* (Fig. 17) is most likely widespread throughout Johor (Grismer and Leong 2005) in lowland forests where it is found on the sides of trees and on leaves. The newly re-discovered *C. sworderi* (Fig. 18) seems at this point, to be associated with lowland forest in the vicinity of central Johor (Daicus and Hashim 2004; Grismer et al. 2007b; Smith 1925). Here, lizards have been found on the ground, on leaves, 3 m above the ground on tree trunks, and in shrubs. All sightings in Endau-Rompin, Johor were in association with stream courses (Grismer et al. 2007b).

Scincidae.—Like the gekkonids, skinks constitute a significant portion of the lizard fauna of SPM, although endemism in this group is far less than that in gekkonids. There are 15 species of skinks confirmed for SPM of which three—*Larutia seribuatensis* Grismer, Leong, and Norsham, 2003, *Sphenomorphus ishaki* Grismer, 2006, and *S. sibuensis* Grismer, 2006—are endemic to the Seribuat Archipelago (Table 1). *Larutia seribuatensis* (Fig. 19) occurs on Tulai and Tioman islands where it is a leaf-litter specialist and emerges to forage above ground shortly following periods of rain (Grismer 2006c). *Sphenomorphus ishaki* (Fig. 20) is a small, leaf-litter inhabitant endemic to the upper elevations of Pulau Tioman and emerges only on cool, overcast days. *Sphenomorphus sibuensis* (Fig. 21), conversely, is found at sea level in the vicinity of mangrove swamps where ambient temperatures are much higher. Both species are rare and virtually nothing is known of their life history (Grismer 2006c).

Squamata (Snakes)

Colubridae.—Despite the relatively high diversity of colubrid snakes (~68 species) in SPM, they are represented by a surprisingly low number of endemics (Table 1), especially when compared to groups like geckos and skinks. Additionally, all the endemic species, except for perhaps one, are restricted to Pulau Tioman of the Seribuat Archipelago. *Calamaria ingeri* Grismer, Kaiser, and Norsham, 2004 (Fig. 22) is known from only two specimens. Both were collected from pitfall traps at 98 m in elevation in lowland dipterocarp forest. *Gongylosoma mukutense* Grismer, Das, and Leong, 2003 (Fig. 23) is a terrestrial, diurnal species that ranges from sea level to near 400 m in elevation in coastal vegetation and lowland dipterocarp forests (Grismer 2006c). *Oligodon booliati* Leong and Grismer, 2004 (Fig. 24) is a terrestrial, leaf litter species that is both diurnal and nocturnal and found primarily in lowland dipterocarp forests (Grismer 2006c). *Macrocalamus* sp. is likely an undescribed species from Endau-Rompin, Johor known only from two, high-quality photographs

given to me by park personnel. The specimen has a color pattern unique to all other known *Macrocalamus*, is the only lowland member of the genus, and represents a southern range extension for the genus of ca. 180 km (David and Pauwels 2004). Based on this, we believe it to be an undescribed species.

Viperidae.—There are seven species of viperids in SPM but the only endemic species, *Popeia buniana* Grismer, Grismer, and McGuire 2006 (Fig. 25), is restricted to Pulau Tioman (Table 1). It is an arboreal, nocturnal species restricted to upland regions of the island above 300 m (Grismer 2006c). It is apparently unique among arboreal pitvipers in that it may be an active forager rather than an ambush predator as inferred from its morphology and anecdotal field observations of its behavior (Grismer et al. 2006c).

CONSERVATION

As noted above, it is clear that the herpetofauna of SPM is understudied and the region incompletely surveyed as underscored by the recent addition of so many new records and the discovery of so many new species in such a relatively short period of time. Although the level of endemism (4%; 5 of 134 species) for continental SPM is low, three of the five endemics were discovered only within the last two years. On the other hand, endemism in the Seribuat Archiplelago is much greater (15%; 17

FIG. 24. *Oligodon booliati*, Pulau Tioman, Pahang. Adult above, juvenile below.

of 111) and like continental SPM, most of its endemics (14 of 17 species) were described only within the last three years.

Based on the results of over a century of field work in montane regions of central and northern continental Malaysia (Boulenger 1900; Das et al. 2004; Das and Norsham 2003; Dring 1979; Grandison 1972; Grismer 2006b, 2007a, 2008a; L. L. Grismer et al. 2004a; Hallerman and McGuire 2001; Leong and Lim 2003; Lim et al. 2002; Matsui and Ibrahim 2006; McLeod and Norhayati

2007; Norsham and Lim 2002; Sanders et al. 2004; Smedley 1931; Smith 1922, 1935; Vogel et al. 2004; Wood et al. 2008a), it is almost certain that field surveys in the montane regions of continental SPM will result in the discovery of additional species, many of which are likely to be endemic, and may raise endemism of these habitat-islands to levels comparable to those of the islands in the adjacent Seribuat Archipelago. What makes the need for field work particularly urgent in continental SPM is that this area has only ca. 35% of its native lowland forest intact and some of this is currently threatened by agricultural expansion. Additionally, some of the islands in the Seribuat Archipelago are threatened by partial deforestation. Pulau Tioman, the largest and most environmentally diverse island in the archipelago, with the highest herpetofaunal diversity and endemism (Grismer 2006c), has suffered a loss of some of its coastal forests to support development of an increasing international tourism industry. The island also has been bisected by a wide, trans-island road that traverses the crest of the island from the west coast at Kampong Tekek to the east coast at Kampong Juara. The road cuts through large tracts of virgin rainforest, making the rainforest interior accessible to other potentially destructive activities. Plans are also in place to construct a runway on the west coast of Pulau Tioman long enough to accommodate large passenger jets. This, and its attendant infrastructure, will have a major negative impact on the coastal and offshore ecosystems. Other islands such as Rawa, Sibu, Tinggi, Aur, and Pemanggil also support a growing tourism industry and its associated environmental degradation.

The herpetofauna of SPM is also under a growing threat of commercialization. Commercial dealers and collectors are hiring native Orang Asli in Johor to collect large quantities of amphibians and reptiles for export and sale abroad. They are also collecting endemics from Pulau Tioman which bring very high prices in the illegal pet trade. One of us (LLG) is often contacted by Malaysian and Indonesian commercial collectors trying to get information about the endemic pitviper *Popeia buniana,* specimens of which are sold for as much as US $400 each.

The documented herpetofaunal diversity of SPM will undoubtedly increase as a result of the ongoing efforts of field biologists working in this area. These increases will be most dramatic in the severely understudied areas of continental SPM as suggested by the recent findings from Endau-Rompin, Johor (Grismer 2006a, 2007b; Grismer et al. 2007b; Wood et al. 2008b). Surveys will also begin in earnest in the upland areas of Endau-Rompin, Gunung Berlumut, and Gunug Ledang and it is expected that many additional records and potentially new species will be discovered here as well. All these areas should be set aside for purposes of studying and preserving the biodiversity of SPM in an effort to protect the natural heritage of Malaysia. Importantly, protected areas such as these can be immensely useful for serving as model systems in evaluating the myriad of complex nuances involved in efficient and cost effective ecosystem management which can subsequently be applied to other imperiled regions of Southeast Asia.

Acknowledgments.—We wish to express thanks to Norhyati A., B. Stuart, Jokor I., and P. Wood for comments on early drafts of the manuscript.

Calamodontophis paucidens (Amaral, 1935) is a rare, slug-eating snake of southern Brazil and Uruguay (Franco et al. 2006). Only twelve specimens were included in the generic summary of Franco et al. (2006). A detailed description of the hemipenis of *C. paucidens* has never been published. Franco (1999) described the species' hemipenial morphology in his doctoral thesis based on one specimen from Cachoeira do Sul, Vila Barro Vermelho (Museu de Ciências e Tecnologia da PUCRS, Porto Alegre, RS, Brazil [MCP] 8607), and a cursory description, based on two males (MCP 7834, 8607), was used by Franco et al. (2006) to compare general characters among other genera of Tachymenini.

Calamodontophis paucidens is scarce throughout its distribution, and only two males are known (Franco et al. 2001; Carreira 2006; Carreira and Meneghel 2004). A detailed description of the hemipenis is an important addition to the knowledge of this scarce species, and can provide useful data to support phylogenetic analyses examining the species' taxonomic position in the Tachymenini.

Materials and Methods

A new male specimen (ZVC-R 6303) from Departamento Rocha, Uruguay, made possible the fresh extraction the left hemipenis and measurements of the position of the right organ *in situ*. The left hemipenis was everted, extracted from the specimen, and injected with a 10% formalin solution. The base was tied off. The hemipenis was maintained in a 10% formalin solution. We used the methods of Zaher (1999) and Dowling (2002).

Results

Specimen information.—Colección Zoología Vertebrados, Reptiles, Secc. Zoología Vertebrados, Facultad de Ciencias, Universidad de la República, Montevideo, ZVC-R 6303: Ruta 109, Camino de las Sierras, 20 km from Rocha city, Departamento Rocha. 16-II-2005. Col.: Gerardo Feijóo (Rocha). Specimen external characters (left/right): supralabials 7(3,4)/7(3,4); preoculars 1/1; postoculars 2/2; temporals 1+2/1+2; infralabials 7(1–3)/8(1–4); ventrals 128; subcaudals 38/39; anal plate divided; scale rows 15/15/15; SVL = 317 mm; tail length = 65 mm; head length = 13.7 mm. Coloration identical to other specimens illustrated in Franco et al. (2001) and Carreira et al. (2005).

Hemipenial description.—The *in situ* organ is 9 subcaudals long, counting from the anal plate. The muscle insertion is at the level of the 28th subcaudal. The organ is slightly bilobed, semicalyculate, and non-capitate, with a spinulate body (Fig. 1). The asulcate surface has spines, smallest on the apical region and slightly enlarged and homogeneous on the body and basal region. The lateral surfaces of the hemipenial body have enlarged lateral spines in the basal region. The *sulcus spermaticus* divides approximately in the middle of the hemipenial body. The intrasulcar region is formed by calyces partially covered with spinulate flounces. These calyces extend outside the intrasulcar region, morphing to spines in the apical zone of the asulcate surface. Flounces weakly differentiated and without spines are observed in the *sulcus spermaticus* division. Calyces extend outside the arms of the *sulcus* on the lobes but never reach the lateral surface. Flounces weakly differentiated are observed in the upper region of the body, on the lateral sides of the *sulcus spermaticus*. The spines on the sulcate surface increase in size towards the basal region, with the exception of the homogeneous row parallel to the sides of the *sulcus*. In the region of the undivided *sulcus*, spines increase in size towards the lateral sides of the hemipenial body. The biggest spines are in the basal region.

Discussion

In his doctoral thesis, Franco (1999) partially described and illustrated the hemipenial morphology of *C. paucidens*. From the drawing in Franco (1999), we can see that the organ in MCP 8607 is not totally everted, because the lobes are largely in contact, and because of the presence of a deep constriction in the middle of the organ that we did not observe in our material. The capture of ZVC-R 6303, the third male known, makes possible the correct preparation and description of the hemipenis and its *in situ* examination.

Franco (1999) recorded 124, 127 (N = 2) male ventrals and

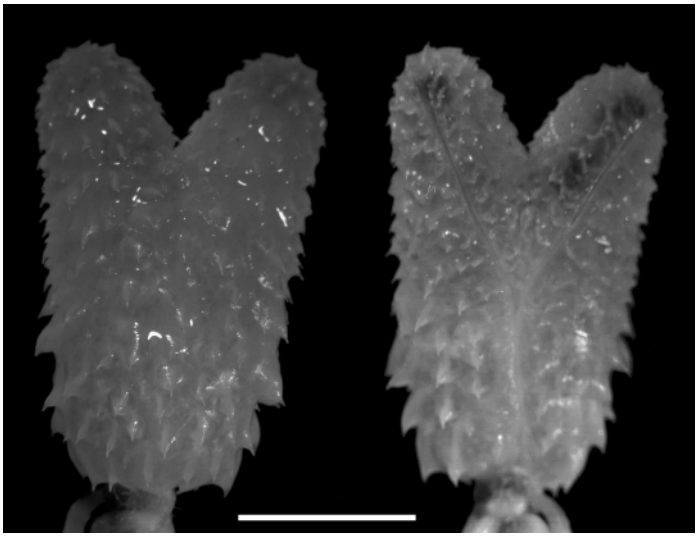

Fig. 1. Hemipenis of *Calamodontophis paucidens* (ZVC-R 6303; scale = 5 mm). Asulcate (left) and sulcate (right) views.

131–137 (N = 9) female ventrals, 32, 39 (N = 2) male subcaudals and 29–32 (N = 9) female subcaudals. Because of only two males, he did not comment on sexual dimorphism. Franco et al. (2001) and Carreira and Meneghel (2004) have data from additional specimens. Carreira and Meneghel (2003) recorded 147 ventrals and 24 subcaudals in the female ZVC-R 5710; we reexamined the specimen and the correct information is 137 ventrals and 32/31 subcaudals. With all of the additional information, we have the following ranges: males (N = 3), ventrals 124–128, subcaudals 32–39; and females (N = 11), ventrals 131–137, subcaudals 29–34. Actually the difference in subcaudal counts is proportionally greater (~12%) than in the ventral counts (~6%).

Acknowledgments.—We are grateful to Gerardo Feijóo for the specimen. We thank Norman Scott for revision of English text and suggestions.

The New World genus *Kinosternon* includes 19 species of small to medium-sized (< 300 mm) aquatic turtles, occurring from southern Canada to Argentina (Ernst and Barbour 1989). The biology of many species of *Kinosternon* has been studied (e.g., Frazer 1991; Gibbons 1983; Iverson 1991; Loben Sels et al. 1997; Morales-Verdeja and Vogt 1997; Vogt and Guzman 1988), but little is known of the biology of *K. scorpioides*. Studies on this species have focused mostly on morphology and information on diet, behavior, and reproduction is limited (Acuña-Mesen 1992; Cabrera and Colantonio 1997; Marquez 1995; Pritchard and Trebbau 1984; Moll 1990).

Current evidence suggests that *K. scorpioides* is a visually oriented omnivore that feeds on fish, amphibians (tadpoles and adults), dead vertebrates, invertebrates, algae and plant material, but with the exception of Moll (1990), most of these data are anecdotal (Cunha 1970; Vanzolini et al. 1980) or based on observation of captives (Monge-Nágera and Moreva-Brenes 1987; Pritchard and Trebbau 1984). In this paper, we describe the diet of *K. scorpioides* at Serra Sul, Floresta Nacional de Carajás, eastern Amazonia.

Materials and Methods.—Serra Sul (6°20'S, 5°25'W) is a narrow plateau (600–800 m above sea level) developed upon a "banded iron formation" at Serra dos Carajás, eastern Amazonia, Brazil (Sifeddine et al. 1994). Climate is seasonal, with most annual rains (1500–2000 mm) falling from November to May. Mean annual temperature is 24°C. Vegetation on the plateau consists mostly of open and shrub savannas ("canga vegetation"), while the steep borders and surrounding lowlands are covered by rainforest. The plateau is covered with many shallow lakes at various stages of silting.

We conducted our sampling in March and April 2005, at the end of the rainy season, when a large part of the study area was flooded. Turtles were captured in lakes, marshes and slow-moving streams, by hand or in Tomahawk live traps (model 202, 47 × 15 × 15 cm) baited with meat and placed partially submerged in water. Traps were checked at 1–6 h intervals. Turtles were sexed, mass was measured with spring scales, and straight-line carapace length (CL) was measured with vernier calipers. All turtles were marked and kept in damp cloth bags for 6 h before release at their capture site. Turtles usually defecated in the bags and these fecal samples were collected and stored in 70% alcohol. We identified each food item to the lowest possible taxon (usually order) and

TABLE 1. Summary of food items found within fecal samples from 23 *Kinosternon scorpioides* (NUM = Sum of individual prey recorded in all feces; IND = Number of individual fecal samples containing a particular prey category; Prey habitat: A = aquatic, T = terrestrial, ? = habitat unknown).

TAXON	NUM	IND	HABITAT
PLANT MATERIAL

Class Mammalia (fur)	1	1	T

counted the total number of each. The number of each prey type present in each sample was considered as the minimum number of individuals that could have contributed to the disarticulated parts (Lima et al. 1997).

Results and Discussion.—We captured 36 *K. scorpioides* a total of 42 times. Our sample included 17 males (mean CL = 123.4 mm, SD = 8.4, range = 96–134 mm; mean mass = 262.7 g, SD = 39.2, range = 150–320 g), 17 females (mean CL = 126.5 mm, SD = 5.8, range = 96.5–135 mm; mean mass = 284.4 g, SD = 62.2, range = 125–385 g), and two unsexed juveniles.

Twenty-eight fecal samples were obtained from 23 turtles. Feces from the same individuals were pooled for the analysis (thus, N = 23). Consistent with previous studies, *K. scorpioides* used a wide range of animal and plant resources (Moll 1990; Monge-Nágera and Moreva-Brenes 1987; Pritchard and Trebbau 1984; Vanzolini et al. 1980). We found 16 different prey taxa in the fecal samples including invertebrates, vertebrates and plant material (Table 1). The most common item was grass seeds (mostly *Echinocloa* sp.), followed by aquatic Hemiptera (*Limnocoris* sp.) and Odonata naiads and adults (Table 1). The most common prey types were aquatic, but some were terrestrial. However, terrestrial prey species were probably consumed in the water, after falling in and becoming trapped (e.g., adult dragonflies; Pritchard and Trebbau 1984). Seeds and other plant material passed undigested through the digestive tract. We do not know if these food items were consumed accidentally or intentionally. However, aquatic plants have been reported in the diet of *K. scorpioides* from Belize (Moll 1990). Captive *K. scorpioides* have been reported to consume vertebrates, including fish, reptiles, and rodents (Pritchard and Trebbau 1984). The rarity of vertebrates in our samples suggested opportunistic feeding, however, we were unable to determine if vertebrates were eaten alive or as carrion. Amphibians were recorded only in three samples, despite being very common within *K. scorpioides* habitat. But our results may have been misleading because amphibians, particularly tadpoles, are easily digested and leave few remains in feces (Daltry et al. 1998).

Acknowledgments.—We thank R. B. Pineschi, R. V. Marques, M. L. Oliveira and M. L. B. Campello for help in fieldwork; R. A. Ribeiro and A. L. Melo for help in prey identification; and S. Neckel-Oliveira and an anonymous referee for helpful comments on earlier drafts of this manuscript. Research was conducted under license from IBAMA (nº 026/2005 CGFAU/LIC) and followed the ASIH/HL/SSAR guidelines for use of live amphibians and reptiles in field research. Field work was funded by Companhia Vale do Rio Doce.

Nomenclatural Status of the Malagasy Snake Genus *Bibilava* Glaw, Nagy, Franzen, and Vences, 2007: Resurrection of *Thamnosophis* Jan and Designation of a Lectotype for *Leptophis lateralis* Duméril, Bibron, and Duméril (Serpentes: Colubridae)

The new generic name *Bibilava* was recently applied to an assemblage of colubrid snakes from Madagascar that had previously been associated with the genus *Liopholidophis* (Glaw et al. 2007; Glaw and Vences 2007), but we here show that the earlier name *Thamnosophis* Jan (1863) is the appropriate name for this group. In addition, we designate a lectotype for *Leptophis lateralis* Duméril, Bibron, and Duméril, the type species of *Thamnosophis*, to resolve some ambiguity in the application of this name.

Mocquard (1904) erected the snake genus *Liopholidophis* to accommodate snakes from Madagascar placed in *Tropidonotus* by Boulenger (1893), primarily because the Malagasy snakes have hemipenes dissimilar to those of *Tropidonotus* with which Boulenger had associated them. Mocquard (1904, 1909) also recognized that several species he included in the genus had an unusually exaggerated sexual dimorphism in tail length (reviewed by Cadle 1996 and Glaw et al. 2007). Apart from the subset of species that shared this unusual sexual dimorphism, *Liopholidophis* came to include other generalized Malagasy colubrids that lacked derived characters linking them to other named Malagasy colubrid genera.

Mocquard (1904) explicitly included the following taxa in *Liopholidophis*: *Leptophis lateralis* Duméril, Bibron, and Duméril, 1854; *Dromicus stumpffi* Boettger, 1881a; *Dromicus sexlineatus* Günther, 1882; *Dromicus dolicocercus* Peracca, 1892; and the new species *Liopholidophis grandidieri* Mocquard, 1904. Subsequent authors (e.g., Cadle 1996; Guibé 1958; Mocquard 1909; Parker 1925) have used Mocquard's name *Liopholidophis* for this assemblage. Williams and Wallach (1989) designated *L. grandidieri* Mocquard (1904) as the type species of *Liopholidophis*; Glaw et al. (2005: 83) erroneously stated that the type species was *L. sexlineatus* (Günther).

Parker (1925) defined two species groups within *Liopholidophis*, which were amplified by Cadle (1996): the *sexlineatus* group for the species having the exaggerated sexual dimorphism in tail length, and the *stumpffi* group for the species lacking that extreme dimorphism. After accommodating subsequently described species and nomenclatural adjustments (Cadle 1996, 1998; Glaw et al. 2005), Parker's *sexlineatus* group comprised the nominal species *sexlineatus*, *dolicocercus*, *grandidieri*, *rhadinaea*, and *varius*, whereas his *stumpffi* group included the nominal species *stumpffi*, *epistibes*, *infrasignatus*, *lateralis*, and *martae*. Cadle (1996) found evidence to support the monophyly of each of the species groups but he suspected that *Liopholidophis* was non-monophyletic because he found no characters to support the monophyly of the genus as a whole. Several authors (e.g., Boulenger 1893; Cadle 1996; Domergue "1972" [1973]; Guibé 1954, 1958; Williams and Wallach 1989), recognized the relevance of the name *Thamnosophis* Jan, 1863 (type species: *Leptophis lateralis* Duméril, Bibron, and Duméril, 1854) to the nomenclature of "*Liopholidophis*" by including the name in the synonymies of *L. lateralis* and *L. stumpffi*. Being the earlier name, *Thamnosophis* has priority over *Liopholidophis* when the two names are applied to the same taxon. However, because Cadle (1996) questioned the relationship of the two species groups of *Liopholidophis* to one another, and the type species of *Liopholidophis* and *Thamnosophis* are in different species groups (*sexlineatus* and *stumpffi* groups, respectively), he chose to leave the generic nomenclature alone until stronger evidence bearing on the systematics of the species groups accrued.

Glaw et al. (2007) provided evidence for the partition of *Liopholidophis* in a molecular phylogenetic analysis of eight species of *Liopholidophis* (three species of the *sexlineatus* group and five species of the *stumpffi* group) along with other representative Malagasy colubrids. They found that each species group was monophyletic. However, species of the *L. sexlineatus* group were more closely related to several species of *Liophidium* than to species of the *L. stumpffi* group, thus making *Liopholidophis* sensu lato non-monophyletic. In revising the nomenclature to conform to their phylogenetic hypothesis, Glaw et al. (2007) restricted the name *Liopholidophis* to the former *sexlineatus* group (which includes the type species, *L. grandidieri*) and described a new species, *Liopholidophis dimorphus*. Glaw et al. (2007) also named a new genus, *Bibilava*, to accommodate species of the former *stumpffi* group and designated, as its type species, *Leptophis lateralis* Duméril, Bibron, and Duméril, 1854.

Thus, Glaw et al. (2007) overlooked the available generic name, *Thamnosophis* Jan, for the *stumpffi* species group. Its type species

(by subsequent designation: Wall 1923:604) is also *Leptophis lateralis* Duméril, Bibron, and Duméril, 1854. *Bibilava* Glaw, Franzen, Nagy, and Vences is thus an objective junior synonym of *Thamnosophis* Jan, which has nomenclatural priority. We resurrect this name, whose nomenclatural history is summarized herewith:

Thamnosophis Jan, 1863

Thamnosophis: Jan 1863:79, 82. Included taxa: *Leptophis lateralis* Duméril, Bibron, and Duméril, 1854; *Leptophis vertebralis* Duméril, Bibron, and Duméril, 1854; *Leptophis bivittatus* Duméril, Bibron, and Duméril, 1854; *Herpetodryas margaritiferus* Schlegel, 1837; *Thamnosophis delesserti* Jan, 1863. Jan and Sordelli 1869: Livr. 31, pl. VI, fig. 3; 1879: Livr. 49, pl. II, fig. 2.

Ahaetulla Gray, part: Boettger 1879:33. Referred species: *A. lateralis* (= *Thamnosophis* Jan).

Philothamnus Smith, part: Boettger 1881b:526. Referred species: *P. lateralis* (= *Thamnosophis* Jan).

Tropidonotus Kuhl, part: Boulenger 1893:193. Referred species: *Tropidonotus stumpffi* (= *Thamnosophis stumpffi*) and *Tropidonotus lateralis* (= *Thamnosophis lateralis*).

Drymobius Fitzinger, part: Boulenger 1894:9, 15, 17. Günther 1885–1902:125. Referred species: *D. margaritiferus* (= *Thamnosophis margaritiferus*) and/or *D. bivittatus* (= *Thamnosophis bivittatus*). See Smith and Smith 1976 for additional citations of *Thamnosophis* in connection with these Neotropical species.

Rhabdophis Fitzinger, part: Wall 1923:604. Referred species: *R. lateralis* (= *Thamnosophis* Jan). [*Leptophis*] *lateralis* Duméril, Bibron, and Duméril, 1854 designated as type species of *Thamnosophis* Jan.

Liopholidophis Mocquard, part: Guibé, 1954:243. Guibé 1958:213. Domergue "1972" [1973]:1397. Williams and Wallach 1989:146. Cadle 1996:416, 421. Referred species: *L. lateralis* (= *Thamnosophis lateralis*) and/or *L. stumpffi* (= *Thamnosophis stumpffi*).

Natrix Laurenti, part: Romer 1956:579. *Thamnosophis* listed as a synonym.

Bibilava Glaw, Nagy, Franzen, and Vences, 2007:294. Glaw and Vences 2007: 438. **New synonymy**.

The name *Thamnosophis* has been used in the combination *Thamnosophis lateralis* (Duméril, Bibron, and Duméril) as a synonym of the Malagasy snakes *Leptophis lateralis* Duméril, Bibron, and Duméril and/or *Dromicus stumpffi* Boettger by the following authors: Boulenger (1893:247–248), Cadle (1996:416, 421), Domergue ("1972" [1973]:1397), Guibé (1954:243; 1958:213), Jan (1863:82), and Jan and Sordelli (1879: Liv. 49, pl. II, fig. 2).

The resurrected genus *Thamnosophis* Jan (1863) has the following content (all endemic to Madagascar): *Thamnosophis lateralis* (Duméril, Bibron, and Duméril 1854) (type species); *Thamnosophis epistibes* (Cadle 1996), new combination; *Thamnosophis infrasignatus* (Günther 1882), new combination; *Thamnosophis martae* (Glaw, Franzen, and Vences 2005), new combination; and *Thamnosophis stumpffi* (Boettger 1881a), new combination. Diagnoses of these taxa are found in Cadle (1996) and Glaw et al. (2005). Characters given by Cadle (1996:417 [Table 2], 436–443, 450–452) for the "*Liopholidophis stumpffi* group" and Glaw et al. (2007:294) for "*Bibilava*" serve as a diagnosis and description of *Thamnosophis*. *Thamnosophis* is diagnosed by unique hemipenial characters, including unusual depressions at the tips of each lobe of the bilobed organs, and lobes set off from the base of the organ by a nude gap, giving the false impression of capitation (Cadle 1996:436–443).

There has been ambiguity in the application of the name *Leptophis lateralis* Duméril, Bibron, and Duméril, the type species of *Thamnosophis*, owing in part to color variation in the type series and confusion about the identity of several nominal taxa we refer to *Thamnosophis*. Resurrection of *Thamnosophis* and reexamination of the syntypes of *L. lateralis* presents an opportunity to resolve this confusion by designating a lectotype for *L. lateralis*. *Leptophis lateralis* was originally described from four syntypes (three females and one male) with the catalogue number 7312 in the Muséum National d'Histoire Naturelle, Paris (MNHN). In a subsequent renumbering, one specimen retained "7312" and the other three were distinguished by letters: 7312A, 7312B, and 7312C. Later, the three specimens with letter designations were given individual catalogue numbers, 1999.8232–8234, corresponding to the letters A–C, respectively.

TABLE 1. Scutellation characters and measurements of the four syntypes of *Leptophis lateralis* Duméril, Bibron, and Duméril. The current identity of each syntype is given below the MNHN number; data for the lectotype are in the first column. Measurements are in mm.

	MNHN 1999.8232 (*Thamnosophis lateralis*) Lectotype	MNHN 7312 (*Thamnosophis lateralis*)	MNHN 1999.8233 (*Thamnosophis lateralis*)	MNHN 1999.8234 (*Thamnosophis epistibes*)
Sex	Female	Female	Female	Male
Total length (SVL)	791 (564)	688 (492)	643+ (503)	680+ (493)
Tail length	227	196	140+	187+
Dorsal scale rows	19–19–17	20–19–17	19–19–17	19–19–17
Ventrals + Preventrals	165 + 1	158 + 2	158 + 2	164 + 2
Subcaudals	95	90	59+	75+
Supralabials (touching eye)	8 (4-5)/8 (4-5)	8 (4-5)/8 (4-5)	8 (4-5)/8 (4-5)	8 (4-5)/8 (4-5)
Infralabials	10/10	10/10	11/10	10/10

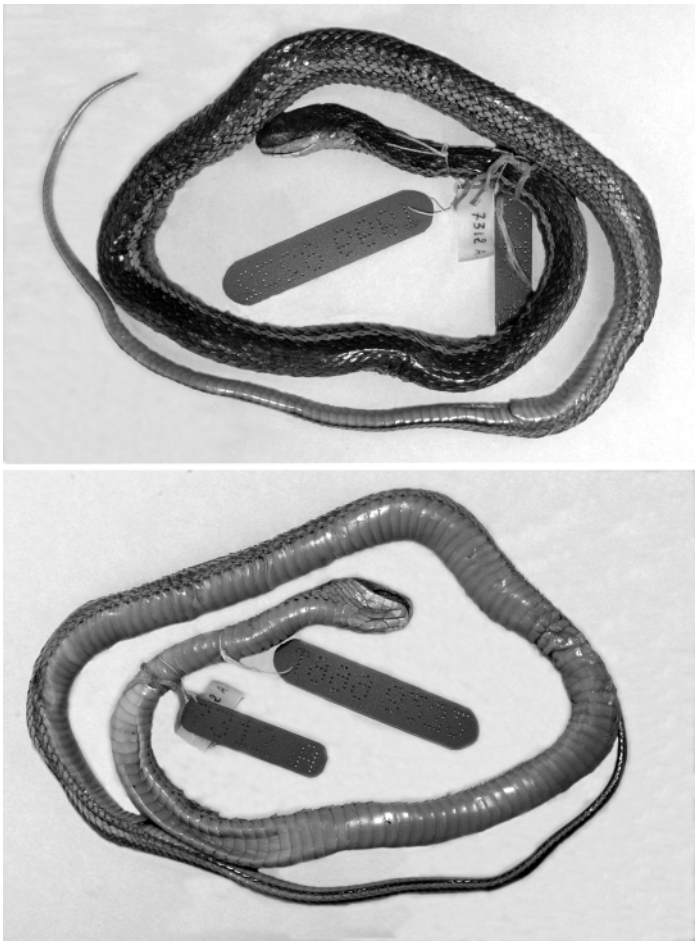

FIG. 1. Lectotype of *Leptophis lateralis* Duméril, Bibron, and Duméril (1854), MNHN 1999.8232, in dorsal and ventral views.

Hereafter, we refer to the specimens by the last numbers. Their scutellation and other traits are summarized in Table 1.

Since its description the name *Leptophis lateralis* has been universally applied to a Malagasy species having a diagnostic color pattern of vivid pale (yellowish to white in life) dorsolateral stripes from the neck to the tip of the tail against a primarily black dorsal ground color. Descriptions and/or illustrations of this form are found in Cadle (1996), Glaw and Vences (1994, 2007), Guibé (1954, 1958), and Jan and Sordelli (1879: Liv. 49, pl. II, fig. 2), among others. However, Duméril et al. (1854:545) indicated that the stripes in one of the syntypes were not so extensive: "The most prominent trait in the disposition of the colors is the presence of a yellowish white band on each side which, in all our specimens with one exception, extend from the head to the tip of the tail." The exceptional specimen is the male syntype (MNHN 1999.8234), in which the dorsolateral stripes are evident on only the anterior quarter of the body. In addition, the male syntype has median black markings on many of the ventral scales (also noted by Guibé [1958:214]), which occasionally form more extensive irregular markings across the anterior edge of individual ventral scales. Neither incomplete dorsolateral stripes nor extensive black ventral markings are characteristic of *T. lateralis*. On the other hand, pale dorsolateral stripes on only the anterior half of the body and/or black ventral markings are characteristic of the other species referred to *Thamnosophis* (i.e., *T. epistibes*, *T. infrasignatus*, *T. martae*, and *T. stumpffi*; see Cadle 1996, Glaw et al. 2005).

The variation in the extent of the dorsolateral stripes among the syntypes of *Leptophis lateralis* has led to some nomenclatural confusion. Some authors have placed *L. lateralis*, in part, in the synonymy of the nominal species *Dromicus stumpffi* Boettger or *Ptyas infrasignatus* Günther (e.g., Boulenger 1893; Cadle 1996) or have considered these species identical (e.g., Guibé 1954, 1958; Mocquard 1904). Guibé (1954, 1958) placed these names and several other nominal taxa in the synonymy of *L. lateralis*, thinking that there was a single, wide-ranging species exhibiting extensive variation in color pattern. This confusion persisted until it was partially sorted out by Domergue ("1972" [1973]) and further resolved by Cadle (1996; see footnote 10). Until now, the syntypes have not been reexamined.

Our study of the syntypes of *Leptophis lateralis* shows that three (MNHN 7312 and 1999.8232–8233) represent the taxon *Thamnosophis lateralis* as universally understood (diagnosis in Cadle 1996). The male syntype (MNHN 1999.8234) is *T. epistibes*, as suspected by Cadle (1996: footnote 10), and has the diagnostic characters of scutellation and color pattern of that species (e.g., ventral spotting, postocular and dorsolateral stripe configurations) (Cadle 1996:386). Although similar to *T. martae*, MNHN 1999.8234 has fewer ventrals than the only known male of *T. martae* (185; Glaw et al. 2005).

We select MNHN 1999.8232 as the lectotype of *Leptophis lateralis* because it is the largest specimen and apparently the one for which Duméril et al. (1854) gave measurements (Fig. 1). The specimen is an adult female in good condition with a midventral slit in the base of the tail. Scutellation and proportions are given in Table 1. The pale dorsolateral stripe of MNHN 1999.8232 extends from the neck to the tail tip. Anteriorly, it is centered on dorsal row four but encompasses adjacent parts of rows three and five; it broadens posteriorly, occupying row four, most of row three, and part of row five. The venter of MNHN 1999.8232 is uniform whitish. Resolution of the identity of the syntypes of *Leptophis lateralis* Duméril, Bibron, and Duméril and selection of a lectotype clarifies the application of this name. Accordingly, the name should be removed from the synonymy of *T. stumpffi* and *T. infrasignatus* (e.g., Cadle 1996) and placed, in part, in the synonymy of *T. epistibes* (Cadle).

Acknowledgments.—We thank Frank Glaw, Charles W. Myers, and Jay M. Savage for comments and advice.

The Mud Dwelling Tadpole of the Long-toed Tree Frog, *Leptopelis xenodactylus* (Arthroleptidae)

ALAN CHANNING
Biodiversity and Conservation Biology Department
University of the Western Cape, Private Bag X17
Bellville, 7535, South Africa
e-mail: achanning@uwc.ac.za

The genus *Leptopelis* includes many terrestrial species (Schiøtz 1999), such as *L. bocagii* and *L. bufonides*. All species studied share a terrestrial breeding system with eggs deposited in nests away from water. The tadpoles wriggle to the water to continue development (Wager 1986, as *Hylambates natalensis*). The tadpoles of many species are found in shallow muddy water.

The Long-toed Tree Frog *Leptopelis xenodactylus* Poynton 1963, is endemic to the midlands of KwaZulu Natal Province, South Africa. Although it was described from a single specimen (Poynton 1963), subsequent specimens (Burger 2004; Van Dijk 1978) have increased the known range to about 120 × 150 km. The species has been placed in the Endangered category of the IUCN, based on its limited and fragmented area (Harrison et al. 2001). This study aimed to locate and describe the tadpole of *L. xenodactylus*, in order that further monitoring and range extensions could be undertaken based on larvae.

The description is based on three specimens collected at Mpur Forest, near Franklin in KwaZulu-Natal Province, South Africa (30°19'56"S, 29°31'04"E). They were collected from soft mud covered by a few mm of water, between grass polls, 15 January 2007, by A. Schmitz and A. Channing. Adults of *Leptopelis xenodactylus* have been collected at this site (Burger 2004; Van Dijk 1978). The habitat was described as a hammock bog and was illustrated in color (Photo 30) by Minter et al. (2004).

Tadpole identification is based on the characteristic low fins and labial tooth row formula, as well as the muddy habitat, characteristic for *Leptopelis* tadpoles. There is only one species of tree frog known from the habitat.

I use the terminology of Altig and McDiarmid (1999), and the morphometric ratios proposed by Van Dijk (1966). Tadpoles were staged according to Gosner (1960). A digital caliper accurate to 0.01 mm was used with a stereo microscope to take the measurements. Measurements were rounded to 0.1 mm. I measured total length, tail length, maximum height of fins, distance from highest point on fin to tail tip, snout tip to spiracle distance, snout tip to nostril distance, internarial distance, distance between eyes, distance between lateral limits of eyes, head width at level of eyes, snout tip to eye distance, nostril to eye distance, width of oral disc, and head width at level of disc.

The three tadpoles were deposited in the Natural History Museum of Geneva, MHNG 2691.53. They have total lengths of 40.2, 38.2, and 20.7 mm, the larger two representing Stage 38 and the smallest tadpole Stage 37. The largest specimen served as the model for the description (Fig. 1). Proportions are given as the range from smallest to largest.

The mouth is positioned ventrally. The oral disc is 59–68% of the width of the head at the level of the disc. The marginal papillae

FIG. 1. Stage 38 tadpole of *Leptopelis xenodactylus*. Scale bar = 10 mm.

are in a double posterior row, with the outer papillae longer, extending well clear of the disc when viewed from the front. The anterior gap in the papillae is 61–71% of the width of the oral disc. The papillae are about twice as long as wide, scattered in the angle of the jaw. The anterior and posterior jaw sheaths are heavy, fully pigmented in the larger specimens, but only the marginal half pigmented in the small tadpole. The jaw sheaths are finely serrated. The labial tooth row formula is 4(2-4)/3 in the larger specimens (Fig. 2), but 2(2)/3 in the small tadpole. The nostrils are rounded with the proximal margin forming a small protuberance. Internarial ratio: width of nostril/internarial distance = 0.17 to 0.33. Longitudinal position of nostrils: rostronasal distance/ orbitonasal distance = 1.29–1.83. There is no orbitonasal line, but a small pineal spot is present midway between the anterior margins of the eyes. Extraocular proportion: width of head minus distance between lateral limits of eyes/distance between lateral limits of eyes = 0.16–0.32.

The spiracle opening is not attached to the body wall, rounded, smaller than the spiracular tube, positioned 70–74% posteriorly along trunk. The vent opening is dextral, confluent with the ventral fin margin. The tail muscle is two thirds as high as the body, with the low dorsal fin only reaching half the height of the tail, and the ventral fin about half the height of the dorsal fin. The tail tip is acutely tapered. The dorsal fin originates just anterior to the junction of the tail and body, rising gradually to a high point 41–48% posteriorly along tail. The extrapolated tail axis passes dorsal to the eyes. Tail length/ length of head and trunk = 2.3–2.7.

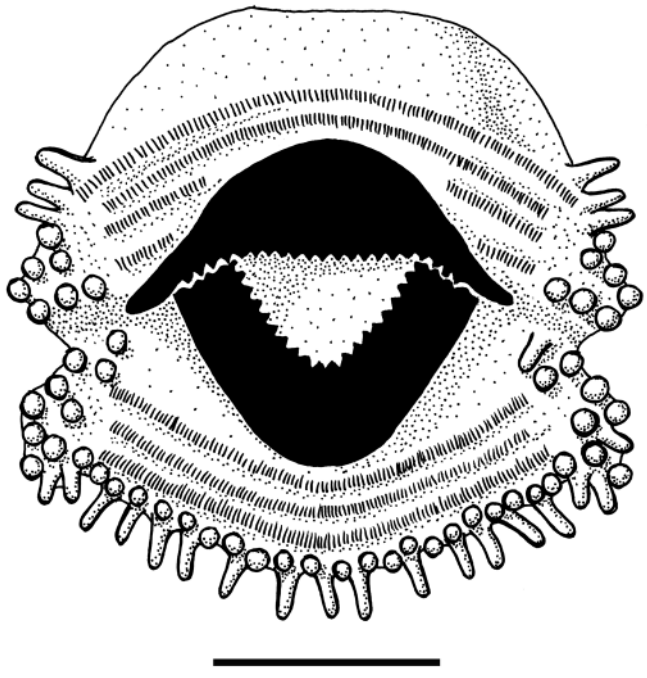

FIG. 2. Mouthparts of Stage 38 tadpole of *Leptopelis xenodactylus*. Scale bar equals 1 mm.

The tadpole is pale with translucent skin, on which very fine black stippling is present, forming irregular clumps over the tail, fins, and lateral and dorsal surfaces of the body. Dark pigment is present over the terminal 25% of the fins, where it forms a black margin on the dorsal and ventral fin margins. The ventral surface of the body is unpigmented.

The measurements of the larger Stage 38 tadpole are: total length 40.2, tail length 29.2, maximum fin height 5.5, highest point on fin to tail tip 15.3, snout tip to spiracle 8.1, snout tip to nostril 2.3, snout tip to eye 3.8, internarial distance 1.7, interocular distance 3.6, width of oral disc 2.4.

Body shape is similar in all known *Leptopelis* tadpoles, which have long tails with low fins. The largest recorded tadpoles are found in *L. gramineus* (Schiøtz 1999) and are 64 mm long, while the smallest are those of *L. hyloides* which are only 34 mm in total length (Oldham 1977).

The labial tooth row formula is known to change as the tadpoles grow, and more rows are added, as documented in *L. calcaratus* (Schiøtz 1999) and *L. nordequatorialis* (Perret 1966). This is apparent in the specimens of *L. xenodactylus*, with the smallest tadpole having two anterior rows of labial teeth, and the larger specimens four rows. The jaw sheaths of *L. xenodactylus* are heavy, resembling those of *Kassina* in build, suggesting that they are able to feed on the tough vegetation.

Previously described tadpoles of *Leptopelis* are all darkly pigmented, such as *L. viridis* (Rödel 2000) although the pigmentation in this species does not extend to the ventral surfaces of the head (Inger 1968). The ventral fins are unpigmented in other species of the genus (e.g., *L. natalensis*, *L. mossambicus*, and *L. oryi* (Inger 1968; Oldham 1977; Wager 1986).

The tadpole of *Leptopelis xenodactylus* can be distinguished from *L. natalensis*, the only other species in the genus likely to be sympatric, by the presence of the dark tail tip.

Tadpoles are useful for monitoring the presence of amphibians. The distinctive tadpole of *L. xenodactylus* is much easier to find than the burrowing adults, which may even vocalize from below ground level. Searching for tadpoles would be an appropriate means of discovering additional localities of this highly cryptic and endangered species.

Acknowledgments.—I thank Marius Burger and Andi Schmitz for assistance in the field.

Social communication in anuran amphibians is predominantly mediated by acoustic signals. However, visual displays have been observed in several species in variable behavioral contexts. Some visual displays were interpreted as part of courtship and/or territorial behavior, especially in diurnal stream dwelling frogs, where the noisy environment hampers acoustic communication (see Grafe and Wanger 2007; Haddad and Giaretta 1999; Hödl and Amézquita 2001; Lindquist and Hetherington 1996; Narvaes and Rodrigues 2005). The functional role of visual displays is so far not well understood, especially in cases where it occurs in nocturnal species and/or in forest dwelling species (e.g., Amézquita and Hödl 2004). As demonstrated recently by various authors (e.g., Giasson and Haddad 2006; Hartmann et al. 2004), visual signaling in nocturnal frogs seems to be more common and is found in many more species than previously thought.

Within the Hylidae, visual displays have been observed in several nocturnal species (e.g., Amézquita and Hödl 2004; Hartmann et al. 2004; Toledo et al. 2007; Zina and Haddad 2007). Frogs of the genus *Phyllomedusa* engage in male-male combat (e.g., De Jesus et al. 2003; Matos et al. 2000; Wogel et al. 2004), and in some species visual signals were reported during combats: *P. hypochondrialis* has been observed to display "hand-waving" (Laurent 1973); leg signals and pedal luring were observed in *P. burmeisteri* (Abrunhosa and Wogel 2004; Bertoluci 2002; Haddad and Giaretta 1999), and foot flagging was reported for *P. distincta* (Castanho 1994) and *P. sauvagii* (Halloy and Espinoza 2000). *Phyllomedusa boliviana* occurs along the dry eastern slopes of the Andes and lowlands of eastern Bolivia to northern Argentina, western Mato Grosso and Rôndonia, Brazil, occupying an altitudinal range of approximately 200–2000 m elev. (Köhler 2000). Its breeding biology has been reported in detail by Vaira (2001). We here report for the first time on visual signaling in *P. boliviana* during male-male interaction and discuss the possible origin of leg stretching behavior in nocturnal anurans.

Materials and Methods.—Observations were made by MJ in an inter-Andean dry valley at Pampagrande (18°05.257'S, 64°06.842'W, 1298 m elev.), Province of Florida, Department of Santa Cruz, Bolivia, on 29 November 2005 (2330 h, 19.7°C air temperature, 60% air humidity). For characters of the general study area see Azurduy et al. (2004) and Ibisch et al. (2004). Males of *P. boliviana* called at a small artificial pond within the small village. Photos and short movie sequences of the behavior, as well as recording of calls were taken with a Minolta Dimage X50 digital camera. A short video sequence was later analyzed on computers. We used the time scale of the Windows Media Player for counting of seconds of leg stretching behavior. Similar observations were done immediately before and during crepuscular light but without torch light. Due to lack of recording we were not able to analyze them adequately.

Results.—Around the pond several males of *P. boliviana* were calling (together with *Pleurodema cinereum*). The behavior of two males observed in a shrub might be classified by the following phases:

Approaching Phase: One male (here called resident, Male A) was calling ca. 150 cm above the water body. The apparent intruder (here called Male B) was sitting less than 10 cm distance from the first, ca. 140 cm above the water body (Fig. 1-1). Male A continued calling, whereby the call type was in agreement with advertisement calls described for *P. boliviana* by Köhler (2000).

Signaling Phase: Nine visual displays were recorded. Male A stretched legs in an alternating manner, whereby stretch displays of one leg had a duration of 5–25 seconds (mean 12.75 ± 8.8; N = 4). The signaling phase itself can be subdivided into four sections: lifting of leg (section I); stretching (section II); movement in an arc backwards and above the body (section III; Fig. 1-2); and bringing back the leg alongside the body (section IV). In the cases where all phases were realized, the total duration of the leg stretching behavior was 13–25 seconds (N = 2). Section III, in which the leg was kept fully stretched and then brought back

FIG. 1. Sequence of male-male interaction and visual display in *Phyllomedusa boliviana* (A, resident male; B, intruding male). 1) Approaching Phase; 2) Signaling Phase (showing leg stretching behavior); 3) Wrestling Phase; 4) Grasping Phase. Photos by M. Jansen.

alongside the body, lasted for 12–19 seconds (N = 2). After a short interval of only 2–4 seconds (N = 2), the other leg was lifted. Calling of Male A continued during visual signaling. Leg movement did not always consist of all the sections described above. In some cases, Male A lifted and stretched the leg entirely without doing an arc, then brought the leg alongside the body (sections I + II + IV; N = 2). This movement was very slow and lasted for about 6 seconds from beginning of the movement to full stretching. Just before wrestling, Male A only lifted the leg, but did not stretch it entirely, then brought it alongside the body (section I + IV; 6 second duration; N = 1).

Wrestling Phase: As Male B slowly continued approaching Male A, the latter initiated a physical combat with a jump forward. This physical encounter consisted of a slow wrestling movement, each male trying to grab the opponent´s head and body with fore and hind limbs (Fig. 1-3). This wrestling lasted for 2:25 minutes, before Male A managed to climb on top of Male B. During wrestling, both males emitted a different call type consisting of short series of pulsed notes, much softer than the advertisement call. This call lasted 400–418 milliseconds (mean = 407 ± 96; N = 3).

Grasping Phase: Wrestling ended in an axillary amplexus with Male A on top (Fig. 1-4). Just after Male A reached the back of its opponent, it was stretching the left leg for 5 seconds, followed by three short, not totally stretched leg-movements, starting with the right foot. The first of these movements lasted 3 seconds, the following were much shorter (about one second). Both males stopped calling, Male B did not try to escape.

Release Phase: Unfortunately, observations ended before Male B was released, but obviously this phase has to follow the grasping phase. Loosening of the grip of the superior male might be triggered by emission of some kind of release call by the inferior male, as reported for *P. sauvagii* by Halloy and Espinoza (2000).

Discussion.—Territorial behavior has been documented for various species of nocturnal hylids, among them several species of the genus *Phyllomedusa*: physical combats appear in *Phyllomedusa boliviana* (Vaira 2001; this study), *P. burmeisteri* (Abrunhosa and Wogel 2004), *P. hypochondrialis* (M. Jansen, pers. obs.; Matos et al. 2000), *P. sauvagii* (De Jesus et al. 2003; Halloy and Espinoza 2000), and *P. rohdei* (Wogel et al. 2004). Our observations are most similar to those described for *P.*

burmeisteri by Abrunhosa and Wogel (2004) or *P. sauvagii* by Halloy and Espinoza (2000).

As stated by various authors (e.g., Haddad and Giaretta 1999; Hödl and Amézquita 2001), the selective pressures leading to the evolution of visual communication in nocturnal anurans are more difficult to understand than in diurnal species. Visual signaling may have evolved in order to avoid physical combat between males and could be as important for the maintenance of spacing among males, to assure well-positioned leaves or facilitate male location by females, as it occurs in the genus *Hyalinobatrachium* (see Hartmann et al. 2005). From our observation, it can be summarized that intraspecific visual signaling in *Phyllomedusa boliviana* occurred in the context of aggressive behavior, was used directionally and displayed toward a target individual, and was accompanied by acoustic signaling. It can be postulated that in a multimodal display of visual and acoustic signals, the acoustic part directs the receiver's attention to the location of the subsequent more informative signal (compare Grafe and Wanger 2007). Furthermore, it can be assumed that the presence of a conspecific competitor triggers the frequency of visual signaling displayed in a directed mode toward the target individual (see Lindquist and Hetherington 1998). These predicted functions of visual and acoustic signals have not been tested in *P. boliviana*.

In the case of *Phyllomedusa* species, such as *P. burmeisteri*, and *P. sauvagii*, visual signaling can be understood as an aggressive display to defend good calling positions and therefore is strongly related to high-quality territories (Abrunhosa and Wogel 2004; Halloy and Espinoza 2000). Defense of an advantageous calling position is known for many arboreal frogs and occurs in several families, e.g., Centrolenidae and Hyperoliidae (Bolivar et al. 1999; Guayasamin and Barrio-Amorós 2005; Passmore and Telford 1981; pers. obs.). One common character in these male-male interactions is some kind of wrestling with close contact of bodies, connected with kicking movements of the hindlimbs, targeted at pushing the competitor from its position. In most of these cases, wrestling and kicking is connected with intense calling activity (e.g., Köhler and Böhme 1996). Thus, it might be postulated that the behavior of foot flagging (sensu Hödl and Amézquita 2001) used as visual signal in arboreal and nocturnal anurans is a derived behavior, originating from a more plesiomorphic kicking movement in male-male combats. It is possibly only a small step from trying to kick a competitor from the twig in direct body contact to "ritualized" leg stretching triggered by the visual and acoustic presence of a conspecific competitor.

Acknowledgments.—We thank A. Langer, Pampagrande, for logistic help. Collecting and exportation permits were provided by the Ministerio de Desarrollo Sostenible, La Paz, and Servicio Nacional de Sanidad Agropecuaria e Inocuidad Alimentaria (SENASAG). P. Herrera and A. Justiniano, Museo Noel Kempff Mercado, Santa Cruz, provided valuable assistance with the permits. We thank W. Hödl for useful comments on a preliminary version of the manuscript. The study was supported by a grant from German Academic Exchange Service (DAAD) and the "Wilhelm-Peters-Fonds" of the Deutsche Gesellschaft für Herpetologie und Terrarienkunde (DGHT) for MJ.

Morelet's Crocodile (*Crocodylus moreletii*) is a large crocodilian (total length [TL] to 416 cm; Perez-Higareda et al. 1991) inhabiting the Atlantic and Caribbean lowlands from northern Mexico southwards to Guatemala and Belize (Groombridge 1987). The scalation of *C. moreletii* has previously been described (Brazaitis 1973; Fuchs 1974; King and Brazaitis 1971; Ross and Mayer 1983; Ross and Ross 1974; Ross and Ross 1987; Smith and Smith 1977), but these accounts are based on samples of specimens collected from widely scattered localities in various range countries, or of unspecified (or unknown) provenance. Additionally, some descriptions are based on small numbers of specimens, perhaps reflecting the overall paucity of large reptiles in museum collections (Barker and Barker 2008). Consequently, published descriptions of *C. moreletii* are of little use for assessing intraspecific geographic variation in meristic characters, such as scalation. This situation is not unique to *C. moreletii* as phenotypic variation in scalation remains undetermined for most species of crocodilians (Ross and Roberts 1979). Indeed, with a few notable exceptions (Hall 1989; Ross and Roberts 1979) there has never been a comprehensive systematic analysis of geographic variation published for any species of crocodilians (Busack and Pandya 2001). Such analyses may identify geographically distinct populations that qualify for taxonomic or legal recognition (Busack and Pandya 2001; Hall 1989; Smith et al. 1997). Furthermore, studies of intraspecific phenotypic variation are an essential prerequisite to our understanding of biogeography, evolution, and ecology (Storer 1982).

Here we describe scalation in a large sample (N = 102) of *C. moreletii* collected in freshwater wetlands of northern Belize (Belize, Cayo, Corozal, and Orange Walk Districts) from 1994 through 1997. Detailed descriptions of this region and our study sites are provided elsewhere (Johnson 1983; Platt 1996; Platt and Thorbjarnarson 2000; Rainwater et al. 1998). We captured crocodiles in conjunction with population surveys (Platt and Thorbjarnarson 2000; Rainwater et al. 1998), and studies of reproduction (Platt 1996), diet (Platt et al. 2002, 2006), and ecotoxicology (Rainwater 2003; Rainwater et al. 2007, 2008). Crocodiles were captured at night with the aid of a spotlight; smaller crocodiles (TL ≤ 100 cm) were taken by hand or dip-net, and a noose-pole was used to capture larger individuals (TL > 100 cm). Each crocodile was permanently marked for future identification by notching the dorsal edge of a unique series of caudal scutes (Jennings et al. 1991) and released at the site of capture within 12 to 24 hours. We also examined two crocodiles that were found dead from unknown causes. The crocodiles in our sample ranged from 34.5 to 260 cm TL. *Crocodylus moreletii* occurs sympatrically with the morphologically similar American crocodile (*C. acutus*) in coastal mangrove habitats of northern Belize and Mexico (Quintana Roo and Yucatán states) and the two species are known to hybridize (Cedeño-Vázquez et al. 2008; Hekkala 2004; Ray et al. 2004; Rodriguez et al. 2008). Although individuals with characteristics of both species have occasionally been reported (Abercrombie et al. 1980; Powell 1972; Schmidt 1924), only crocodiles exhibiting the irregular subcaudal scale groups that are typical of *C. moreletii* (Platt and Rainwater 2005; Ross and Ross 1974) were included in our study. It is important to note that in reptiles, meristic characters such as the number of scales are determined during embryonic development (Ferguson 1985; Kerfoot 1970; Ross and Mayer 1983), and other than increasing in size, scales do not exhibit postembryonic ontogenetic change (Busack and Pandya 2001).

Scale counts and nomenclature follow Brazaitis (1973), King and Brazaitis (1971), and Ross and Ross (1987). We counted the following scale groups on each captured *C. moreletii*: post occipital scales, nuchal scales, dorsal scale rows (counted from posterior edge of nuchal cluster to posterior margin of hind limbs), continuous scales in each dorsal scale row, ventral scale rows (counted from the first row posterior to the ventral collar to the last complete row anterior to the cloaca), double-crested caudal

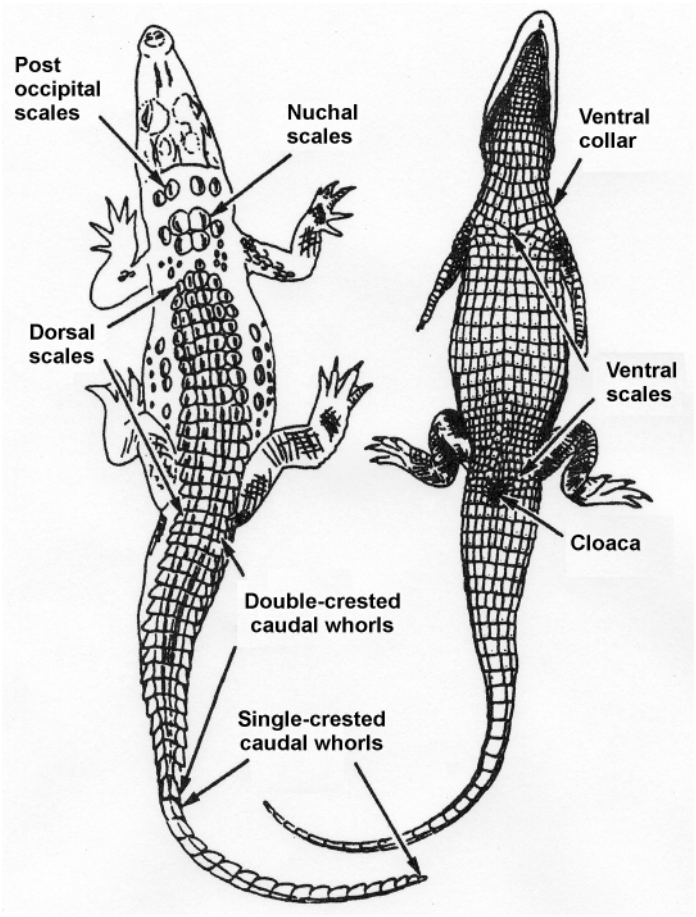

FIG. 1. Generalized dorsal (left) and ventral (right) view of a crocodile showing major scale groups, ventral collar, and cloaca. Transverse dorsal scale rows are counted from the first row posterior to the nuchal cluster to the posterior margin of hind limbs. Ventral scale rows are counted from the first transverse row posterior to the ventral collar to last complete row anterior to the cloacal margin. (Drawing modified from Brazaitis 1973).

whorls, and single-crested caudal whorls (Fig. 1). We calculated the mean number of dorsal scales for individual crocodiles as the sum of the scales in each row divided by the number of rows. To calculate the overall mean number of dorsal scales for our sample, we summed the total number of dorsal scales and divided this value by the total number of transverse rows. Mean values are presented as ± 1SD and results were considered significant at $P \leq 0.05$.

We found little variation in the number of post-occipital scales among our sample of *C. moreletii* (mean = 4.0 ± 0.4; range = 3–6); 92 (90.1%) crocodiles had four scales, while two (2.0%) were missing an element, and eight (7.8%) had either one (4) or two (4) extra elements. The range of post-occipital scales that we found is slightly greater than the range of four to six reported by others (Brazaitis 1973; Fuchs 1974; Smith and Smith 1977). However, post occipital scalation was considerably more variable among a sample of 100 specimens from throughout the geographic distribution of *C. moreletii*; 64 crocodiles had four post-occipital scales, while 36 had additional elements (range = 4–7) (Ross and Ross 1987). Using data from Ross and Ross (1987), we calculated a mean of 4.5 ± 0.8 post-occipital scales for this sample. This value is significantly greater than the mean number of post-occipital scales among *C. moreletii* from Belize (One-tailed *t*-test, $t = 5.03$, $df = 152$, $P < 0.001$).

With a single exception, the nuchal scale group in our sample of *C. moreletii* consisted of two tandem pairs of enlarged scales flanked by a smaller scale on each side. One crocodile in our sample lacked the two smaller flanking scales, and flanking scales were present, although considerably reduced in two other crocodiles. The number and arrangement of nuchal scales in *C. moreletii* from Belize is consistent with most published accounts (Brazaitis 1973; Fuchs 1974; Ross and Ross 1987; Smith and Smith 1977). Ross and Ross (1987) report a slightly larger range (4–8) in the number of neck shield (= nuchal) scutes, although only 11% of their sample deviated from the modal value of 6.

The mean number of transverse dorsal scale rows among *C. moreletii* from northern Belize was 15.9 ± 0.3 (range = 15–17). The same range is given by others (Brazaitis 1973; King and Brazaitis 1971; Smith and Smith 1977), but mean values are unavailable for comparison with our data. The mean number of dorsal scales in each transverse row ranged from 3.4 ± 0.6 to 5.0 ± 1.1 (N = 102 crocodiles). The overall mean number of dorsal scales in each transverse row was 4.3 ± 0.9 (N = 1624 dorsal scale rows). The minimum and maximum number of scales in any single dorsal row ranged from 1 to 4 and 4 to 6, respectively (frequency distribution in Table 1). The maximum number of scales in each dorsal row is given as 3–6 by others (Brazaitis 1973; Ross and Mayer 1983; Smith and Smith 1977). To our knowledge, comparable data on the minimum number of scales in each dorsal row have not been published.

The mean number of transverse ventral scale rows among the *C. moreletii* that we examined was 31.5 ± 1.5 (range = 28–37). Mean values for ventral scalation have not been previously reported for *C. moreletii*; however, the range that we found is somewhat greater and encompasses the range of 29–33 given by Brazaitis (1973). The mean number of double- and single-crested caudal whorls among *C. moreletii* from Belize was 17.3 ± 0.6 (range = 16–19) and 20.0 ± 1.0 (range = 16–22), respectively.

TABLE 1. Frequency distribution of the minimum and maximum number of scales in each dorsal scale row of *Crocodylus moreletii* (N = 102) collected in northern Belize (1994–1997). Number of crocodiles followed by percent of N in parentheses.

	Number of scales					
	1	2	3	4	5	6
Minimum	2 (1.9)	34 (33.3)	38 (37.2)	28 (27.4)	0	0
Maximum	0	0	0	1 (0.9)	13 (12.7)	88 (86.2)

Mean values for double- and single-crested caudal whorls are unavailable for comparison with our data. The range of 17–20 double-crested caudal whorls reported elsewhere for *C. moreletii* (Brazaitis 1973; Smith and Smith 1977) is somewhat greater than we found in Belize. According to Brazaitis (1973), *C. moreletii* is characterized by 19 (range not given) single-crested caudal whorls, the median value of our sample. The distal-most single-crested caudal whorls appeared to be missing or deformed (probably as a result of past injuries; Webb and Messel 1978) in many of the *C. moreletii* that we examined making comparisons of this character among populations problematic.

In conclusion, our study constitutes the first quantitative description of scalation among *C. moreletii* from a specific, well-defined geographic region. A comparison of our data with the few published accounts suggest that interpopulational differences in scalation may exist among *C. moreletii*, although whether populations can be identified on the basis of scalation remains to be determined. Differences between our data and published descriptions were noted among post occipital, dorsal, and ventral scale groups. Interestingly, a cursory examination by SGP and TRR of a small number of *C. moreletii* at a crocodile farm in Villahermosa, Mexico, suggests that at least in dorsal scalation, these animals differed from conspecifics in Belize. However, a complete analysis of geographic variation in scalation among *C. moreletii* must await the publication of comparable data from other range countries.

Acknowledgments.—We are grateful for the logistic support of Robert Noonan and the staff of Gold Button Ranch, and Monique and Mark Howells of Lamanai Outpost Lodge. Support for SGP and JBT was provided by the Wildlife Conservation Society. TRR and STM were supported by U.S. EPA (Grant no. R826310 to STM), and an ARCS Foundation (Lubbock, Texas Chapter) scholarship to TRR. Additional support was generously provided by the Royal Geographical Society, Richard and Carol Foster, Monkey Bay Wildlife Sanctuary, Cheers Restaurant, Stanlee Miller, and Sul Ross State University. The field assistance of Lewis Medlock, Travis Crabtree, and Steve Lawson was essential to the success of our project. Research permits were issued by Raphael Manzanero and Emile Cano of the Conservation Division, Forest Department, Belmopan, Belize. Comments from Lewis Medlock and two anonymous reviewers improved an early draft of this manuscript.

The limestone islands of the Pulau Banggi (ca. 07°14–19'N, 117°5–10'E) group are situated off the northeast coast of the island of Borneo, and due south of the Philippines islands of Balabac and Palawan (Fig. 1). In geographical terms, they lie between the basins of the South China Sea and that of the Sulu Sea, and cover a total land area of 699 km^2. Banggi, the largest of these islands, is ca. 700 km^2 in area and has a coastline of 420 km (Teh et al. 2005). Other important islands of the group include Balambangan and Malawali, the former island with extensive limestone formation, with outcrops reaching 120 m (Tuen et al. 2002). Administratively, these islands fall under Kudat District of Sabah (East Malaysia), and are included in the proposed (in 2003) Tun Mustapha Marine Park, designated primarily to protect the rich marine life of the surrounding seas. The archipelago comprises about 70 islands, 33 of which are inhabited by an estimated 80,000 people of various ethnic origins (Biusing 2001).

The first naturalist recorded to have collected on these islands is Francis Henry Hill Guillemard (1852–1933), in 1883, on board the 420-ton auxillary screw yacht 'The Marchesa,' which visited islands of eastern Asia and New Guinea on a natural history expedition. Although the purpose of the stop at Banggi was to obtain fresh water, Guillemard also made a collection of birds (Chasen and Boden Kloss 1930). In 1886, Alfred Hart Everett (1849–1898), then Resident of Trusan, Sarawak, and formerly with the British North Borneo Company, an important collector of Bornean fauna, visited these islands, and again made ornithological collections. The earliest herpetological collection took place on these islands in 1927, organized and led by Cecil Boden Kloss (1877–1949) of the Raffles Museum, Singapore, in collaboration with Henry Maurice Pendlebury (1893–1945), systematic entomologist with the Federated Malay States Museum. Besides the archipelago, the Expedition also worked in adjacent mainland, in what was then the Residencies of Sandakan and Kudat. Material from these collections is extant in the collection of the ZRC. However, little has been published on the herpetofauna of the region, apart from the citation of a specimen of *Bronchocela cristatella* in Tan (1993).

We report here the results of two separate inventories, undertaken in 2003 by the first author on Pulau Balambangan in the month of June, and by the second author on Pulau Banggi, in July. Lowland limestone forests characterize these islands, and include forests of tall trees of the Dipterocarpaceae, besides *Calophyllum* spp. and *Ficus* spp., growing sometimes on steep cliffs, besides limestone cliffs and coastal, sandy beaches (descriptions in Rahman and Abdullah 2002). As sampling periods were short (2–5 days), we employed opportunistic collection methods, such as collections along established trails and adhesive traps, rather than pit-fall trapping, searches in leaf-litter plots, and time constrained searches. We also examined specimens in museum collections to augment our list.

Abbreviations used include:

BOR.– The Borneensis Collection of Universiti Malaysia Sabah (including collections of Universiti Kebangsaan Malaysia, UKMS), Kota Kinabalu, Sabah, Malaysia,

ID.– The field collection number of the first author,

SSM.– Sabah State Museum and Archives, Kota Kinabalu, Sabah, Malaysia, and

ZRC.– Zoological Reference Collection, Raffles Museum of Biodiversity Research, National University of Singapore, Singapore (USDZ in Leviton et al. 1985). For one specimen, the voucher specimen (prefixed with ZRC [IMG]) is a digital image.

Nomenclature of amphibians follows Frost et al. (2006) as revised by Frost (2007); that of the Pythonidae follows Rawlings et al. (2008).

AMPHIBIANS

FAMILY DICROGLOSSIDAE

***Limnonectes kuhlii*:** BOR 12409–12411, BOR 12413–12418, Sungai Kepitan, Kampung Kalangkaman, Pulau Banggi (07°18'N, 117°5.2'E), 27 July 2007.

***Limnonectes leporinus*:** BOR 12408, Sungai Kepitan, Kampung Kalangkaman, Pulau Banggi (07°18'N, 117°5.2'E), 27 July 2007; ZRC 1.12152 (*ex* ID 7779), west coast of Pulau Balambangan (07°12'N, 116°45'E), 18 June 2003.

FAMILY MICROHYLIDAE

***Kalophrynus pleurostigma*:** ZRC 1.12151 (*ex* ID 7772), bank of an unnamed freshwater stream on west coast of Pulau Balambangan (07°12'N, 116º45'E), 18 June 2003.

***Microhyla borneensis*:** BOR 12402, Kampung Kalangkaman, Pulau Banggi (07º18.5'N, 117º5.16'E), 26 July 2003.

FAMILY RHACOPHORIDAE

***Polypedates macrotis*:** ZRC 1.10885, *ex* ID 7773, west coast of Pulau Balambangan (07º12'N, 116º45'E), 18 June 2003.

***Rhacophorus appendiculatus*:** BOR 12405–07, BOR 12412, Forest path nr. Kampung Kalangkaman, Pulau Banggi (07º18'N, 117º5'E), 27 July 2007.

***Rhacophorus pardalis*:** BOR 12401, BOR 12404, Forest path nr. Kampung Kalangkaman, Pulau Banggi (07º18'N, 117º5.1'E), 26 and 27 July 2007, respectively.

FAMILY RANIDAE

***Hylarana raniceps*:** BOR 12403, BOR 12419, Sungai Kepitan, Kampung Kalangkaman, Pulau Banggi (07º18'N, 117º5.2'E), 27 and 28 July 2007, respectively.

REPTILES

FAMILY AGAMIDAE

***Bronchocela cristatella*:** BOR 02721, Pulau Balambangan (cited by Tan 1993:2) (no further sampling data).

FAMILY GEKKONIDAE

***Gekko gecko*:** SSM 0383, Pulau Balambangan; ZRC 2.5732 (*ex* ID 7948), west coast of Pulau Balambangan (07º12'N, 116º45'E), 19 June 2003; UKMS (at present BOR) Re. 443, ZRC 2.1018–1023, "Pulau Banggi" (no further sampling data).

***Gekko monarchus*:** ZRC 2.6557 (*ex* ID 7776) and ZRC 2.6558 (*ex* ID 7778), west coast of Pulau Balambangan (07º12'N, 116º45'E), 18 June 2003.

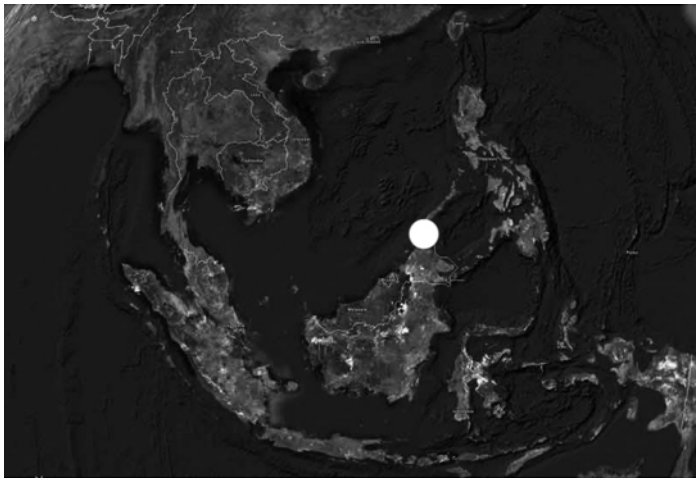
FAMILY SCINCIDAE

***Apterygodon vittatum*:** ZRC 2.6559 (*ex* ID 7774), west coast of Pulau Balambangan (07º12'N, 116º45'E), 18 June 2003.

***Emoia atrocostata*:** ZRC 2.1564, Pulau Banggi (no further sampling data); west coast of Pulau Balambangan (07º12'N, 116º45'E; I. Das, field sighting, 21 June 2003).

***Eutropis multifasciata*:** UKMS (at present BOR) Re. 391, Wak Wak, Pulau Banggi, Kudat District (07º08'N, 117º06'E); UKMS (at present BOR) Re. 402, Selamat Darat, Pulau Balambangan, Kudat District (07º15'N, 116.56'E) (no further sampling data).

FAMILY ELAPIDAE



***Laticauda colubrina*:** Tan (2008) recorded this species from Pulau Banggi.

FAMILY PYTHONIDAE

***Broghammerus reticulatus*:** ZRC 2.3143–3147, Pulau Banggi (no further sampling data).

FAMILY COLUBRIDAE

***Boiga dendrophila*:** ZRC [IMG] 2.64, west coast of Pulau Balambangan (07º12'N, 116º45'E), 20 June 2003. Tan (2008)

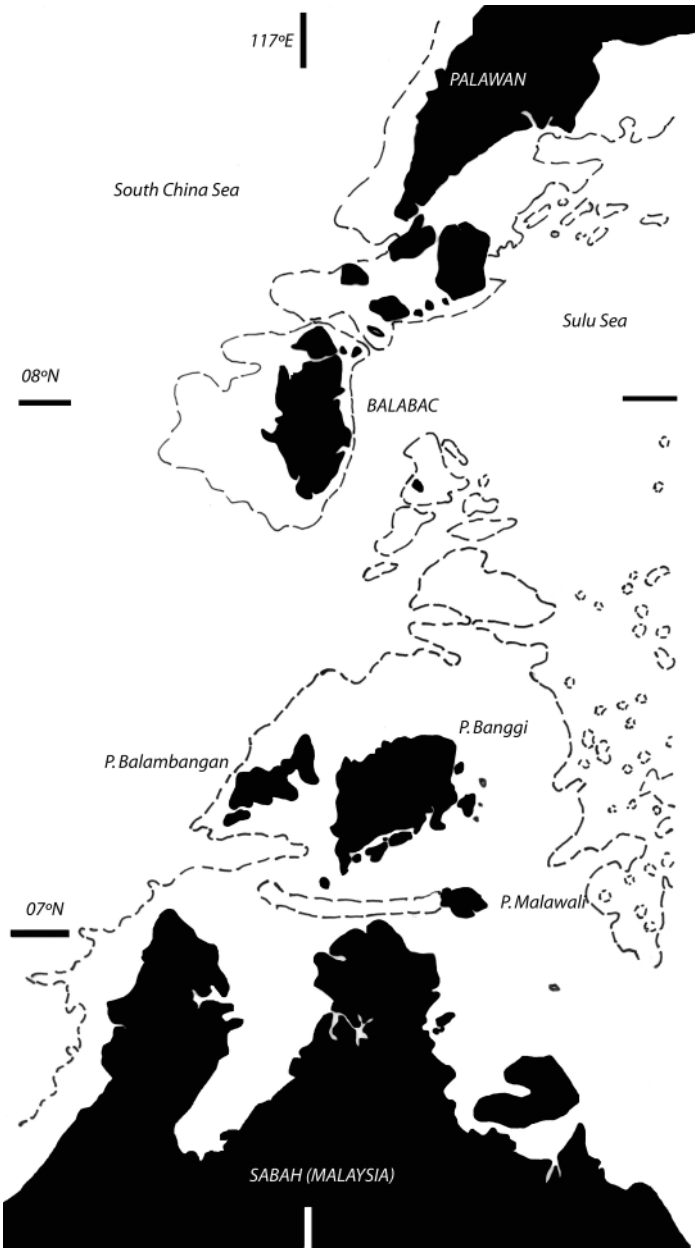


FIG. 1. Maps (on left) of Borneo and (on right) of the Pulau Banggi group of islands, Kudat District, Sabah, off the northeast coast of Borneo, and the islands of southern Philippines. Broken lines indicate 40 m contour.

presented an image of this species from Pulau Malawali.

***Chrysopelea paradisi*:** ZRC 2.3599, Pulau Banggi (no further sampling data).

***Dendrelaphis caudolineatus*:** ZRC 2.6560 (*ex* ID 7777), west coast of Pulau Balambangan (07º12'N, 116º45'E), 18 June 2003.

FAMILY CROCODYLIDAE

***Crocodylus porosus*:** Not collected, but reported by the local Bajau tribesmen as occurring off the waters of Pulau Balambangan.

Excluding marine turtles, for which no data are currently available, Pulau Banggi and adjacent islands are home to at least eight species of amphibians and 12 species of reptiles. All, save one (*Gekko gecko*), are widespread across the lowlands of Borneo, a distributional pattern similar to that shown by the island group's avifauna (Chasen and Boden Kloss 1930). The sole reptile not known from Borneo is widely distributed in the Philippine Archipelago, and may either be a recent emigrant via the Palawan-Balabac corridor, or competitively excluded on the main island by the closely related and presumably ecologically similar *Gekko smithii*. The islands to the north of the Pulau Banggi group lie within the jurisdiction of the Philippines, and the herpetofaunas of Palawan and Balabac has been enumerated by Mocquard (1890) and Boulenger (1894).

Acknowledgments.—We are grateful to Sabah Parks for permitting us to work in an area under its jurisdiction and the Royal Malaysian Police for escort. ID is grateful to Fatimah Abang for invitation to participate in the 2003 UNIMAS Expedition to Pulau Balambangan, and to Fatimah Abang, Dennis Hill, Colin Treadaway, Malcolm Page, Sarol Hamzah, and Rizan Abdullah, for support and friendship. KBH is thankful to Miou B. Enot, Headman of Kampung Kalankaman, for permission to sample, Azlin Abd. Hamid for help at Pulau Banggi, and David Meja, Rajan Madawat, and Jalan bin Ukang, for their assistance in the field. We are also grateful to Kelvin K. P. Lim and Peter K. L. Ng, for facilities at ZRC (USDZ), and to Joseph Pounis Guntavid and Anna Wong, for permission to examine the collection of the SSM. Kraig Adler provided biographical details of historical collectors. Two anonymous reviewers provided comments on the manuscript, and Kelvin K. P. Lim and Tan Heok Hui for a copy of an article from 'Rod & Line'. Finally, we are grateful to our respective institutions and their Directors, Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak (Andrew Alek Tuen), and the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah (Maryati Mohamed), for support of our research on the herpetofauna of Borneo.

Tadpoles are studied in a variety of fields including husbandry, developmental physiology, toxicity testing, and basic biological and ecological research. In many instances it is necessary to use gloves when handling tadpoles or during water changes to protect the experimenter (e.g. teratology research) or to promote hygiene and prevent the transfer of pathogens between tadpoles (Retallick et al. 2006; Sobotka and Rahwan 1999). While investigating aspects of the virulent amphibian fungal pathogen *Batrachochytrium dendrobatidis*, we discovered that a variety of gloves can be lethal to tadpoles. We present here two case studies, one in the lab and one in the field, and two experiments, all demonstrating the lethal effect of gloves on tadpoles. Following exposure to the

various glove treatments, all tadpoles were categorized as either fine, listless, or dead.

Case Study 1: Laboratory

Batrachochytrium dendrobatidis infects the skin of frogs, but only the mouthparts of tadpoles (Knapp and Morgan 2006; Marantelli et al. 2004). During a laboratory experiment investigating *B. dendrobatidis* infection in *Litoria genimaculata* and *Litoria nannotis* tadpoles, each tadpole was to be measured, weighed, and its mouthparts swabbed with a sterile cotton swab to test for *B. dendrobatidis* by diagnostic PCR (Boyle et al. 2004). A new pair of latex gloves (SuperMax, low powder) were worn when handling each tadpole to prevent transmission of *B. dendrobatidis* between individuals and to prevent DNA contamination of swab samples. Each tadpole was scooped out of its container with a gloved hand. The tadpole was secured, ventral surface up, in between the index and middle fingers by gently depressing the thumb to the base of the tail. A swab was gently passed over the mouthparts repeatedly to collect *B. dendrobatidis* DNA on the cotton fibers. Each tadpole was in hand for approximately 30–90 seconds before being returned to its container.

Thirty-six *L. genimaculata* had been processed in this way when we observed that some of the earliest handled tadpoles appeared listless, could not remain upright, and had difficulty using their tails for locomotion. Upon closer inspection, the tails of the listless tadpoles were gray and dead in appearance at the locations where gloved fingers held them in place during swabbing. At that time, we suspended tadpole handling. Within 24 h, 26 of the 36 tadpoles died. The surviving ten tadpoles did not appear listless, showed no overt adverse effects and survived 4–6 weeks to metamorphosis (Fig. 1A). Although care was taken to handle tadpoles gently, the observed mortality could possibly have been due to mechanical damage, so we initiated a series of experiments. Based on the results of these experiments (see below), we switched from latex to vinyl gloves for the remainder of the lab study. Ten unhandled *L. genimaculata* and *L. nannotis* tadpoles were processed as previously described except with vinyl instead of latex gloves. Following 24 h of observation, no mortality or ill effects were noted. Satisfied that vinyl gloves were safe for tadpoles of these species, the remaining 13 *L. genimaculata* and 22 *L. nannotis* tadpoles were processed using vinyl gloves (Fig. 1A). All tadpoles appeared unaffected after handling. In total, 26/36 *L. genimaculata* died following handling with latex gloves, while 0/23 *L. genimaculata* and 0/32 *L. nannotis* died following contact with vinyl gloves.

Experiment 1: Glove Soak

To determine the best gloves for handling tadpoles, we conducted an experiment testing the three most common glove types: latex (SuperMax, low powder), vinyl (Livingstone, clear, low powder), and nitrile (Livingstone, low powder). Forty non-native *Bufo marinus* tadpoles were captured from a local pond and allowed to rest in individual 1000 mL containers with 500 mL of collected rainwater and a pinch of powdered tadpole chow (3:1 alfalfa pellets:fish food, ground and passed through a 250 μm sieve). After 24 h, one of each glove type was draped over the edge of the container for five minutes so that the five fingers of each glove were submerged. Ten control containers had no contact with a glove. The condition of each tadpole was recorded at 2, 12, 24, and 72 h following removal of the glove, however, tadpole condition did not change beyond the two hour post-exposure point. One of ten tadpoles exposed to the latex gloves died and two more were listless and floating awkwardly within two hours of glove exposure. One of the tadpoles exposed to nitrile gloves was listless while all of the vinyl and control treatments appeared unaffected (Fig. 1B). The listless tadpoles remained in an impaired state for the full 72 h of observation and appeared permanently affected. These listless tadpoles were euthanized and preserved in 70% ethanol. Although three of the ten *B. marinus* tadpoles exposed to latex gloves experienced deleterious effects, the rate of mortality was lower than we expected given the high level of mortality we previously observed in *L. genimaculata*. We hypothesized this difference was related to the different methods of glove exposure. The *L. genimaculata* in "Case Study 1" were in direct physical contact with the gloves during measuring and swabbing while the *B. marinus* in "Experiment 1" were in water in which gloves were soaked. This indirect glove contact may have yielded a lower dose of the toxic compound(s).

Experiment 2: Glove Contact

To determine whether direct glove contact increases mortality, we ran a second experiment in which *B. marinus* tadpoles were handled in the same manner as previously described for *L. genimaculata* and *L. nannotis*. Each tadpole was gently held in place at the base of the tail between the thumb and index finger for 60 seconds with one of the three types of gloves as treatments or with an ungloved hand as a control. A new glove was worn for each tadpole and the treatments were interspersed, with each glove type and the bare hand treatment applied in succession. Prior to the no glove treatment, hands were rinsed in tap water and dried with a paper towel to remove any residual powder from the previous glove treatment.

Within two hours of handling, all tadpoles that had been in contact with latex or nitrile gloves were dead or listless. Those that were listless died within 24 h (Fig. 1C). Listless tadpoles had little to no tail function and the usually dark black tail had a discolored, dead-looking, gray appearance. This discoloration was most pronounced where direct contact with the gloves occurred. Particles in the water soon began to attach to the epidermis of the dying tail, giving it a fuzzy appearance. None of the tadpoles handled with either vinyl gloves or bare hands suffered noticeable ill effects and all survived to metamorphosis (Fig. 1C).

Case Study 2: Field

We applied our conclusion that vinyl is the safest glove material to "Case Study 1: Lab" (described above) as well as a field study monitoring *B. dendrobatidis* in the wild. Individual tadpoles were to be captured, handled with vinyl gloves, measured, swabbed for *B. dendrobatidis* infection, and returned to the stream unharmed. During initial field sampling, individuals were processed and kept temporarily in a holding tray to monitor condition following swabbing. Unexpectedly, of the first ten *L. nannotis* tadpoles processed, four became listless and died within one hour (Fig. 1D). The remaining six tadpoles appeared normal and did not develop signs over the following 24 h. As a test, the next ten captured tadpoles were processed with bare hands and suffered

no ill effects, suggesting the gloves and not the handling were the cause of mortality. The next ten captured tadpoles were processed with vinyl gloves that were rinsed in a bucket of water prior to handling. All of these tadpoles survived and appeared normal suggesting that a substance on the outside of the vinyl glove was toxic and that rinsing successfully removed it. All tadpoles were held for 24 h for observation. From this point on we incorporated the rinsing of vinyl gloves into the standard field protocol. Vinyl gloves were rinsed in a 10 L bucket of water which was changed after at most ten tadpoles. This was adequate to ensure the glove-wash residue did not attain a high enough concentration to cause harm. To date over 2500 tadpoles have been handled with washed vinyl gloves with no ill effects. On a few occasions, the rinsing step was accidentally skipped and many of these tadpoles became listless and died.

The fact that the same type and brand of vinyl glove did not cause mortality in *L. nannotis* tadpoles in the laboratory trials but did cause mortality in the field suggests that the presence or level of the toxic compound(s) may vary among boxes of gloves. This may be a result of varying conditions during glove fabrication. During production of disposable gloves, a large number of chemicals are added including vulcanizers, accelerators, colorants, preservatives, stabilizers, and antistatic agents (Boman et al. 2004). These chemicals are typically the cause of glove sensitivity in humans. The type and quantity of these compounds can vary widely among manufacturers and possibly even production runs (Boman et al. 2004).

Our results show that unwashed latex, nitrile, and vinyl gloves can be toxic to tadpoles. Unwashed latex and nitrile gloves caused up to 100% tadpole mortality following only 30–90 seconds of direct contact (Fig. 1C). Rapid, localized necrosis of tissue at the point of contact was observed grossly. Even five minutes of partial glove submersion was sufficient to cause mortality in the latex and nitrile treatments (Fig. 1B).

Despite a thorough literature search, only two references to the toxic effects of gloves on tadpoles were found and both of these were published in toxicological journals, likely to have low readership by herpetologists. In a letter to the editor, Sobotka and Rahwan (1999) reported that water from unwashed latex gloves (American Dental Association, Safeskin brand) and washed latex gloves (Baxter Pharmaseal Flexam) soaked for 24 h caused mortality in *Xenopus laevis* tadpoles. However, water from washed vinyl gloves (Baxter Triflex) did not. Gutleb et al. (2001) reported 100% mortality in *X. laevis* and *Rana temporaria* tadpoles exposed to water from unwashed latex gloves (Becton-Dickinson) soaked for 24 h. Even very dilute solutions of glove-soaked water (0.29% for *X. laevis* and 0.15% for *R. temporaria*) caused 100% mortality. Gutleb et al. (2001) found that vinyl gloves (Becton-Dickinson) soaked for 24 h also killed tadpoles, but only at relatively high concentrations: 33% and above. Mortality was 100% at or above this concentration but 0% below this concentration.

Our results, together with the results from these published studies, demonstrate the potentially high toxicity of latex gloves to tadpoles. Different brands of latex gloves, different exposure methods, and tadpoles of different species were used in each study. Sobotka and Rahwan (1999) tested washed and unwashed latex gloves. The end result, however, was the same: significant

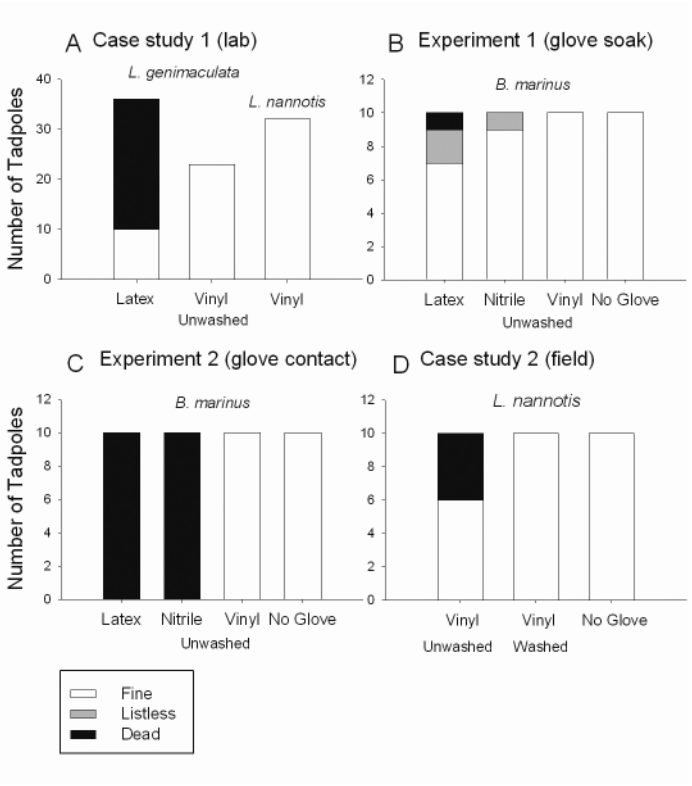

FIG. 1. A) Case Study 1: Laboratory. Number of *Litoria genimaculata* and *Litoria nannotis* tadpole deaths within 24 h following contact with latex or vinyl gloves for 30–90 seconds. B) Experiment 1: Glove Soak. Number of *Bufo marinus* tadpole deaths within 72 h following contact with water containing latex, vinyl, and nitrile gloves soaked for 5 minutes. C) Experiment 2: Glove Contact. Number of *B. marinus* tadpole deaths within 24 h following direct contact with latex, vinyl, and nitrile gloves and bare hands for 60 seconds. D) Case Study 2: Field. Number of *L. nannotis* deaths within 24 h following direct contact with unwashed vinyl gloves, washed vinyl gloves, and bare hands for 30–90 seconds.

tadpole mortality. This suggests that glove toxicity may be associated with many different brands of disposable latex glove and tadpoles of many different species are likely to be affected. Ours is the first report that nitrile gloves can also be extremely toxic to tadpoles, producing 100% mortality in *Bufo marinus* following direct glove contact.

We found that unwashed vinyl gloves can also cause mortality, however, at a lower rate than either latex or nitrile gloves. This finding is supported by Gutleb et al. (2001) who found that vinyl glove-soaked water caused mortality only at dilutions over 110 times more concentrated than latex glove soaked water. Importantly, by rinsing the vinyl gloves in water we eliminated any obvious toxicity.

As a result of the apparently more toxic nature of latex and nitrile gloves compared with vinyl, and the ability to eliminate toxicity in vinyl gloves through rinsing, we recommend the use of well rinsed vinyl gloves when handling tadpoles or cleaning aquaria. However, all glove brands and types are potentially toxic and should not be used until proven safe with tadpoles of the particular species being handled. Even then, handled tadpoles should be observed carefully as toxicity may vary between production runs.

It is important to note that gloves have not been found to affect juvenile or adult amphibians negatively. The use of gloves to handle amphibians is widespread in the field and lab. Changing gloves between amphibians remains an important hygiene measure to prevent transmission of infectious agents such as *B. dendrobatidis* and ranaviruses between individual amphibians and aquaria. However, given our tadpole results, it would be useful to investigate potential non-lethal effects of gloves on adult and juvenile amphibians to ensure that gloves really are entirely non-injurious.

Acknowledgments.—We thank Bryan Windmiller and Jamie Voyles for providing helpful comments on an earlier draft of the manuscript. This work was supported by the Department of the Environment and Heritage (Australia) tender 42/2004 and 43/2004. The techniques and experiments used here were approved by the Animal Ethics Committee at James Cook University, Townsville (A930, A960 and A970). Permits to collect and capture tadpoles were granted by Queensland Parks and Wildlife Service (WISP03070205, WITK 03070205 and INN/004).

Studies in population ecology require use of reliable marking techniques to estimate various parameters (e.g., population size, density, demographics, movement, or behavior; Penney et al. 2001; Perret and Joly 2002; Walsh and Winkelman 2004; Woods and Martin-Smith 2004). However, it is imperative that marking techniques meet standard assumptions: 1) marks must remain visible for the duration of the experiment, 2) marks are correctly recorded, 3) marks do not affect the survival of the animal, and 4) marks do not affect the recapture probability of animals (Goldsmith et al. 2003; Otis et al. 1978).

Visible implant fluorescent elastomer (VIE; Northwest Marine Technology, Inc., Shaw Is., Washington, USA) was initially developed for batch marking migratory fish, but has recently been used to mark amphibians and lizards (Bailey 2004; Losos et al. 2004; Nauwelaerts et al. 2000; Nishikawa and Service 1988; Penney et al. 2001). Visible implant fluorescent elastomer consists of a liquid polymer added to a curing agent to create a flexible plastic mark. Color kits are available, capable of marking 15,000 individuals depending on the number of colors used and marking design. Our objective was to determine if VIE was an appropriate marking technique for snake research based on the marking assumptions of Otis et al. (1978) and Goldsmith et al. (2003). We hypothesized that VIE would be a reliable marking technique for snakes. To our knowledge, our study is the first to apply VIE to snakes.

We conducted this empirical study in a laboratory setting at North Carolina State University, Raleigh, North Carolina, USA. We marked Red Cornsnakes (*Pantherophis guttatus*; N = 18) between 19 and 29 April 2006. Each snake received three doses (1, 2, and 3 μl) of yellow VIE randomized to the general area of three locations (neck, midbody, and pre-caudal). We injected marks subcutaneously and dorsolaterally on left sides using a graduated 1cc Luer-lok syringe with a 25-gauge needle (Becton-Dickinson, Franklin Lakes, New Jersey, USA). We used 1cc syringes to better approximate volumes, which required the 25-gauge needle for a secure fit. We injected additional *P. guttatus* (N = 4) and Common Kingsnakes (*Lampropeltis getula*; N = 6) with

blue and red to examine VIE color, ground color, and species effects, but did not quantify results from these 10 snakes.

All snakes were captive-raised and housed individually at a constant 26.6°C with food, water, and substrate provided regularly. We checked snakes for marks every two weeks using a UV-B light. We collected shed skins to record shedding frequency and expulsion of marks. Our study concluded on 4 May 2007 after 370 days.

We calculated retention time as the number of days we detected a mark until the median date between when a mark was last detected and the following examination. We derived mean retention times for each mark volume (1, 2, and 3 μl). To discern the effects of mark volume or individual variation on retention time, we analyzed retention time as a dependent variable with mark volume and individuals as independent variables in an additive, 2-factor analysis of variance (ANOVA). Similarly, we employed two 1-factor ANOVAs with retention time as the dependent variable and shedding frequency (i.e., number of sheds/individual) or mark location (i.e., neck, midbody, and pre-caudal) as independent variables. We performed analyses using PROC GLM (SAS 9.1, Cary, North Carolina, USA). We calculated the percentage of marks retained to demonstrate mark performance by volume.

All 18 *P. guttatus* used in the experiment were of similar length (mean = 990.39 ± 79.41 mm snout–vent length) and weight (mean = 370.33 ± 81.93 g). After 370 days, 94, 83, and 100% of low (mean = 354 days), medium (mean = 333 days), and high (mean = 370 days) mark volumes were retained. A 2-factor ANOVA revealed no differences in retention time between mark volumes ($F_{2, 34} = 1.27$, P = 0.2940) or individuals ($F_{17, 34} = 0.88$, P = 0.6045). Shedding frequency (mean = 5.05 ± 1.21 sheds/snake) did not have a significant effect on mark retention time at low ($F_{1, 16} = 0.79$, P = 0.3860), medium ($F_{1, 16} = 0.00$, P = 0.9501), or high mark volumes (100% retention). Analysis of mark location revealed a 13% lower mean retention time for marks located pre-caudally (mean = 321 days) compared to neck (mean = 366 days) and midbody (mean = 370 days) mark locations. However, we did not detect a significant difference in mark retention among mark locations ($F_{2, 51} = 3.00$, P = 0.0588).

Our results indicated that VIE was a reliable marking technique for snakes, with 94, 83, and 100% retention for low, medium, and high volumes after 370 days and no mortalities recorded. Elastomer marks were easy to identify and record due to fluorescent colors. We observed a lower retention time for pre-caudal marks. In fact, three of the four marks lost (1-low and 2-medium volume) were located in the pre-caudal region and were lost through expulsion within the first few examinations. If we removed these early loses from our analyses, retention times would be 100, 94, and 100% for low, medium, and high volumes, respectively.

Our results demonstrated that VIE marks last at least 370 days and satisfy the marking assumptions proposed by Otis et al. (1978) and Goldsmith et al. (2003). Branding and scale clipping have been reported to last ≥ 3 years (Brown and Parker 1976; Winne et al. 2006) and elastomer marks have been reported lasting well over a year in amphibians (Davis and Ovaska 2001) and are capable of permanence (Kinkead et al. 2006). We acknowledge our short study duration (370 days), but believe VIE satisfies assumptions for correct recording, and survival and recapture effects (Davis and Ovaska 2001; Kinkead et al. 2006) and is a reliable marking technique for snakes. Equipment costs were initially higher for VIE (US $465) compared to scale clipping (i.e., scissors) or branding (i.e., cautery units ~US $20–25; Winne et al. [2006]), but marking costs per snake were small (~$0.10– $0.29 for marks of 1– 3 μl). Further, our retention of all mark volumes suggested the usefulness of VIE in snakes of any size; small marks can be applied to small-bodied species and individuals (≤ 26 cm), which may be too small for PIT tags or scale clipping (Spellerberg 1977). However, problems were encountered with the technique. Pre-caudal marks had a 13% lower retention time and accounted for 75% of marks lost. Mark losses occurred from 23 days to 310 days, and were likely due to expulsion from the site of injection. Similarly, fragmentation of marks into several pieces could cause detection problems. The application of a liquid bandage product would likely deter expulsion and pathogen introduction.

We recommend future studies evaluate the use and efficacy of VIE in snakes, both in lab and field settings. Future studies should evaluate using VIE in different species of snakes with various ground colors and at various mark locations. Anecdotally, we can report that yellow, blue, and red VIE colors were detectable in Red Cornsnakes at all volumes, but blue VIE was difficult to detect in Common Kingsnakes due to the dark ground color of this species. Mark volume should be studied in the field to better understand mark retention under natural conditions and field and laboratory research should focus on survival and recapture rates for VIE over longer periods. Future research should evaluate the effects of growth on mark detectability and compare stress levels incurred by traditional and VIE marking techniques.

Acknowledgments. — Facilities and procedures for research regarding captive snakes followed the guidelines for the Institutional Animal Care and Use Committee at North Carolina State University (Approval Number 05-036-0). Pond breeding amphibians require terrestrial habitat during the non-breeding season in addition to aquatic reproductive habitat. Ambystomatid salamanders such as spotted (*Ambystoma maculatum*) and marbled salamanders (*Ambystoma opacum*) have been previously studied to determine migration movements and terrestrial habitat requirements. Several migration studies have estimated the "life" or buffer zones required for terrestrial non-breeding habitat. Estimates of habitat area that encompass 95% of the population have ranged from 159 m to 370 m (Faccio 2003; McDonough and Paton 2007; Rittenhouse and Semlitsch 2007; Semlitsch 1998; Semlitsch and Bodie 2003). Few studies have examined migration and non-breeding home range of *Ambystoma* species over multiple years because of the difficulties of long term tracking and monitoring of these animals. Recent studies have shown that vertebrates with implanted passive integrated transponder (PIT) tags are detectable subterraneously (Cabarle et al. 2007; Kuhnz 2000). The purpose of this study was to examine the utility of PIT tags and a multidirectional radio frequency identification (RFID) antenna system (FS 2001 Destron reader and Biomark triangle antenna) for tracking and monitoring ambystomatid salamanders during the non-breeding season.

Identifying and locating individual salamanders is important in determining terrestrial home range and migration. Several methods of identification have been used including: photographs of spot patterns (Stenhouse 1985), toe clips (Ott and Scott 1999), radiotelemetry (Faccio 2003; Madison 1997; McDonough and Paton 2007), PIT tags (Blackwell et al. 2004; Gibbons and Andrews 2004; Ott and Scott 1999), and subcutaneously implanted reflector tags (Moseley and Castleberry 2005). Drift fences have been frequently used to monitor migrants to and from breeding pools (Kleeberger and Werner 1983; Sexton et al. 1990). Concentric circles of drift fences spaced at regular intervals allow researchers to determine the approximate area in which salamanders establish a home range. However, drift fences only capture salamanders moving on or just below the surface. Radiotelemetry studies can track animals underground, but transmitters have a short (< 5 months) battery life and can have high cost (> US $150 each). Radioisotopes were used to determine the home range and summer movements of *A. maculatum* (Kleeberger and Werner 1983), *A. talpoideum* (Semlitsch 1983), *Plethodon jordani* (Madison and Shoop 1970), and *Desmognathus fuscus* (Ashton 1975), but do not allow for individual specific identification.

Materials and Methods.—In this study we attempted to locate and track ambystomatid salamanders using RFID antenna systems with animals that had been marked during previous reproductive seasons with PIT tags. The study area was a constructed vernal pool on the Tennessee Valley Authority's (TVA) South Holston Weir Dam property (36.5239°N, 82.1100°W) in Sullivan County, Tennessee, USA. The floodplain forest at this location supports populations of both *A. maculatum* and *A. opacum*, with the population of *A. opacum* being distinct and disjunct in eastern Tennessee (Hamed et al. 2007). A two-lane paved road (Holston View Dam Road) bisects the property and salamanders living on the north side of the vernal pool must cross the road to reach the pool. The forested area (0.79 ha) north of the road consists mainly of Virginia Pine (*Pinus virginiana*), Boxelder (*Acer negundo*), and Sycamore (*Plantus occidentalis*). A mixed deciduous forest composed mainly of Sweetgum (*Liquidambar stryaciflua*), Sycamore, White Oak (*Quercus alba*), and a 0.5 ha patch of non-native bamboo (*Phyllostachys aureosulcata*) border the south side of the vernal pool.

Previous studies have reported variable detection distances of PIT tagged vertebrates beneath the soil surface (12–22 cm) in both *in situ* (Kuhnz 2000) and experimental (Cabarle et al. 2007) conditions. The observed variability was a result of antenna sensitivity and environmental conditions. We first used a preserved specimen of *A. maculatum* obtained from the East Tennessee State University teaching collection to determine the sensitivity of subterranean detection of PIT tags specific to our study site in a series of ten location accuracy trials. A TX-1411-SST PIT tag (Biomark, Idaho) was injected into the body cavity of the preserved specimen anterior to the rear limbs. To

test detectability of location with the antenna we placed a PIT tag implanted preserved salamander on the forest floor in the leaf litter where it was not visible. The specimen was also buried 5 cm, 10 cm, 15 cm, 20 cm, 25 cm, 27.5 cm, and 30 cm below the surface at the same location. All soil initially removed for burial of the specimen was replaced so as to maintain the naturally occurring soil density. The soil type at this location was well drained Pettyjon loam in a floodplain, derived from limestone and shale (USDA 2008). A waterproof twelve inch triangular, multi-directional, RFID antenna with 10' pole and Destron FS 2001 PIT tag reader with attenuation control box (model AN-TN-04 Biomark) was used to locate the specimen. Biomark technical representatives reported that 25 cm was the maximum detection distance under factory conditions. In order to determine movement patterns of individual animals correctly, it was necessary to identify the actual position of the marked animal and to determine the accuracy of the detection system under the given soil and environmental conditions. The observer moved the antenna in a side to side motion at a rate of ca. 0.5 m/sec. Following initial detection of the transponder the observer then attempted to mark the correct position of the salamander by noting the location at which the specimen was first and last detected as the antenna was moved horizontally across the forest floor. The middle of this range was marked as the location of the specimen. The specimen was then uncovered and the distance from the marked location determined. Ten successive trials at each depth were conducted. In four of these trials using a PIT tagged preserved specimen, the maximum distance above the ground that the antenna could detect the buried specimen was measured using a tape measure before the specimen was unearthed. In these four trials the antenna was held immediately above the identified point and slowly raised until the signal was no longer detected. This measurement provided an estimate of the depth of the specimen below the surface by subtracting the measured height of the antenna above the soil surface from the antenna's maximum detection depth (27.5 cm).

On 20 October 2006, 30 *A. opacum* salamanders were captured by hand as they crossed Holston View Dam Road during the return migration from the vernal pool, and in drift fences in the forest bordering the south side of the pool. On 28 February 2006 and 16 March 2007, 18 and 94 *A. maculatum* respectively were captured along the Holston View Dam Road. On 16 March 2007, an additional 78 *A. maculatum* were captured in pitfall traps in an area south of the vernal pool. These 78 salamanders were not expected to be found in the PIT tag study area to the north of the vernal pool in subsequent surveys. Overall a total of 220 individuals were tagged, of which 190 were *A. maculatum*. All animals were subsequently immersed in a 1% solution of MS-222 (tricaine methanesulfonate) buffered to pH 7.0 at room temperature until anesthetized, and a 12-gauge sterile syringe was used to insert a TX–1411–SST PIT tag (Biomark) into the body cavity of the salamander just anterior to the rear limbs. The wound was sealed with VetBond™. Animals were subsequently released in the center of the vernal pool. All animals appeared healthy at the time of release.

One-quarter of a hectare of the forested area north of Holston View Dam road was divided into a grid of 5 m × 5 m quadrats on 27 July 2007. This area is 36 m from the release site at the center of the vernal pool and is bordered on one side by the road, on two sides by parking areas, and by the South Holston River on the fourth side. These barriers create a discrete patch of useable habitat. The entire search area falls within the terrestrial buffer zone of 164 m recommend for amphibians (Semlitsch 1998) and therefore all PIT tagged individuals were potentially present throughout the area. Each 5 m × 5 m quadrat was completely searched with overlapping sweeps of the antenna to insure that the entire 0.25 ha grid was covered. Surveys were conducted on five separate dates resulting in a total of 11 h of effort. Downed logs were turned over and areas under the logs were searched. When PIT tags were detected the location and depth of the salamander was estimated by the same method used in the previous trails with a preserved specimen. Location was determined by noting the point at which the antenna initially detected the PIT tag and then the point at which the antenna no longer detected the PIT tag as the antenna was moved horizontally across the surface. Depth was estimated by measuring the maximum distance above the ground at which the antenna could detect the PIT tag and then subtracting this distance from the maximum 27.5 cm depth detection distance determined for the antenna under these conditions in the previous trials using a preserved specimen. Exact locations of individual animals were then marked with numbered surveyors flags. Each marked location of an identified salamander was then checked during subsequent surveys and any change in position was marked and measured as a straight line distance relative to the most recent known position of that animal. Distance to the edge of the vernal pool was measured for each *A. maculatum* detected. Four PIT tag detection points were examined for the presence of a live salamander. The leaf litter was searched and a shovel then used to carefully remove soil at the detection point. The soil was scanned with the antenna until the salamander or transponder was found. Salamanders were returned to a small mammal runway adjacent to the disturbed area and covered with leaf litter after discovery. The remaining tag detection points were not examined because of the potential negative effects of stress and desiccation on animals disturbed during the then prevailing extreme drought conditions (NOAA 2008).

Results.—The PIT tag in the preserved *A. maculatum* was detected in all ten trials up to 27.5 cm below ground. One trial located the tag at 30 cm below the surface. The mean deviation between the actual location and the predicted location at different depths varied from 11.7 cm to 21.3 cm. In unobstructed, open-air conditions above the tag, the antenna detected the tag a mean of 29.7 cm above the tag (range = 27.7–38.6 cm) (95% CI = 26.2–33.3) (Table 1).

Eleven percent (12 of 112) of the PIT tagged *A. maculatum* were detected in the study area. Eleven of the 12 A. *maculatum* were individuals that had originally migrated to the vernal pool from the north side of the pool. The twelfth individual was originally captured in drift fences to the south of the vernal pool. After being released in the pool this individual apparently migrated 142 m in the opposite direction (north) from its original capture location. For *A. maculatum* the recapture rate of marked salamanders was 9.8% (discounting the twelfth individual that migrated from the south side of the vernal pool). For *A. opacum* the recapture rate of PIT tagged salamanders was 3.3% (1 of 30). A total of eleven hours of surveying time was expended in locating the 13 PIT tags recovered in the study area with a resulting detection rate of

1.18 individuals per hour of surveying effort. The mean distance from the edge of the vernal pool to non-breeding habitat traveled by *A. maculatum* was 58.7 m (range = 41.1–72.3 m; 95% CI = 51.0–66.4). The mean estimated depth of *A. maculatum* was 6.8 cm below the forest surface (range = 2.0–15.0 cm; 95% CI = 4.02–9.61).

Three of four excavated PIT tags revealed a living *A. maculatum*. The fourth tag had been originally placed in a living *A. opacum* and was recovered without the salamander being found. The three excavated *A. maculatum* moved an average of 8.4 m from their original locations, after being excavated and then placed in a small mammal runway close to the point of capture. Tracking of *A. maculatum* with PIT tags over a seven-week period suggested a very limited home range in late summer (< 0.5m^2) within the restrictions of PIT tag antenna location distance and within the confines of this study. The 12 *A. maculatum* observed within the 0.25 ha surveyed were using a total of 0.24% of the available habitat. Eight of the 12 salamanders were found in two separate groups of four clustered in an area of 8 m^2 each.

Discussion.—The FS 2001 PIT tag reader and triangle RFID antenna were shown to detect a preserved *A. maculatum* with a PIT tag 27.5 cm below the surface in 100% of the ten location accuracy trials. On only one occasion could the tagged preserved specimen be detected at 30 cm below the surface, so 27.5 cm was considered the maximum depth of PIT tag detection at the study site. Previous studies involving PIT-tagged fossorial vertebrates were able to locate the California Legless Lizard (*Anniella pulchra*) under field conditions at depths of up to 12 cm with less sensitive RFID antenna systems (Kuhnz 2000), and Tiger Salamanders (*Ambystoma tigrinum)* under controlled conditions where specimens in cloth bags were covered with soil up to 22 cm deep using the same RFID antenna system as in this study (Cabarle et al. 2007). Radioactive tags injected into *Plethodon jordani* have been detected at depths of up to 50 cm (Madison and Shoop 1970) but could only be detected in *A. maculatum* at depths of 25–30 cm using Cobalt 60 (Kleeberger and Werner 1983). Radioactive tags do not allow for individual specific identification of salamanders. The 27.5 cm maximum depth detected in this study would have located most *A. talpoideum* from a previous study, which ranged in depth from 2.5–7.5 cm (Semlitsch 1981). *A. maculatum* are thought to inhabit similar depths (Semlitsch and Bodie 2003). Studies using radio-implanted transmitters did not report a depth but salamanders were found in shallow small mammal runways underground and in leaf litter (Madison 1997). With the possible exceptions of deep winter burrows used by *A. maculatum* (Faccio 2003), PIT tagged ambystomatid salamanders seem to inhabit soil depths that can be surveyed throughout the summer and during breeding migrations.

In this study the "recapture rates" (i.e., detection of RFID signals) of PIT tagged *A. maculatum* was 9.8% and *A. opacum* was 3.3%. There were 1.18 captures per hour of effort in covering an area of 0.25 ha during 13 h of surveying. Previous studies of ambystomatid salamanders using other marking techniques had recapture rates during the first year of 35.7% for PIT tag studies using drift fence recapture (Blackwell et al. 2004), and 52.6% to 75% for radiotelemetry studies (Faccio 2003; Madison 1997; McDonough and Paton 2007; Montieth and Paton 2006) , and 17% after 100 days for radioisotope based studies (Semlitsch 1981). The lower rates of detection of marked individuals in this study are likely attributable firstly to the difficulty of detection in summer habitat without the use of drift fences and secondly to exceptional drought conditions present during the time of this study (NOAA 2008) that may have driven the salamanders to unusually deep depths beneath the soil surface and beyond the range of the RFID antenna (> 27.5 cm).

The preserved PIT-tagged *A. maculatum* specimen was identified a mean distance of 11.7–21.3 cm from its actual location in our location accuracy trials, depending on the depth at which the specimen was buried. This degree of accuracy would allow individual specific daily or weekly movements to be reliably observed. Radioactive tags allowed *A. talpoideum* to be detected with 10 cm accuracy (Semlitsch 1981) as could radio-implanted transmitters used to locate *A. maculatum* (Madison 1997).

The cost of PIT tagging and tracking individual *A. maculatum* using the latest generation RFID triangular antenna may be more overall cost effective than other options for many applications. PIT tags cost ≤ US $5.00 each (Biomark, Idaho) when purchased in bulk. Radio tags used in other studies cost US $160 each (BD-2 model Holohil Systems, Ontario, Canada). The triangular RFID antenna and tuning box for PIT tags cost approximately US $4,900 (Biomark) compared to antennas for tracking radio transmitters that cost US $650 (Holohil). The total cost to tag and track 200 *A. maculatum* with PIT tags would be about US $5,900, while the total cost to mark and track the same number of *A. maculatum* with radio transmitters would be about US $32,000.

Radioisotopes require an extensive regulatory infrastructure and have a limited effective lifespan compared to PIT tags. Radio transmitters typically have a battery life of 5–6 months which requires recapture, transmitter removal, battery replacement, and transmitter reimplantation (Faccio 2003; Madison 1997; McDonough and Paton 2007). However, PIT tags function for over 10 years and can be detected after the salamander dies

TABLE 1. Mean linear accuracy from the point of detection of the PIT tagged preserved specimen to the actual location, and mean predicted depth below the soil surface of the PIT tagged preserved specimen based on the height above the identified location that a PIT tag signal was detectable.

Pit Tag Depth	Mean Linear (95% CI) Accuracy (cm)	Mean Predicted Depth (95% CI) Below Surface (cm)
Leaf Litter	12.6 (10.7–14.4)	+0.7 (+8.7–7.32)
5 cm	13.1 (11.4–14.8)	2.9 (+0.7–6.5)
10 cm	13.2 (11.7–14.7)	7.6 (3.2–12.1)
15 cm	15.1 (11.9–18.4)	8.9 (2.4–15.3)
20 cm	11.7 (9.1–14.2)	14.1 (5.8–22.5)
25 cm	13.7 (11.4–16.0)	18.5 (15.7–21.3)
27.5 cm	16.7 (11.9–21.4)	19.6 (17.9–21.4)
30 cm	21.3 (10.9–31.6)	18.4 (16.4–20.4)

(Gibbons and Andrews 2004).

The mean distance *A. maculatum* migrated from the breeding pond was 58.7 m. Movements greater than 150 m were not possible because of a barrier created by the South Holston River. Previous studies have produced variable estimates of mean post reproductive migration distances: 64 m (Williams 1973), 92 m (Kleeberger and Werner 1983), 113 m (Faccio 2003), 118 (Madison 1997), and 145 m (Montieth and Paton 2006).

Based on the distance above the surface that PIT tagged *A. maculatum* were detected, the mean estimated depth occupied in summer habitat was 6.8 cm (range = 2.0–15.0 cm; 95% CI = 4.02–9.61 cm). Other studies have shown that *A. maculatum* can be found as deep as 1.3 m (Gordon 1968) and at this depth these salamanders could not be detected by any current tracking method. *A. talpoideum* has been shown to inhabit burrows that averaged 4.7 cm below the surface (Semlitsch 1981). The 12 salamanders we followed for seven weeks showed little detectible change in location or depth. This lack of activity could have been the result of extreme drought conditions (1.5 cm total rainfall) during the seven-week study period (NOAA 2008).

In our study *A. maculatum* has a non-breeding home range of less than 0.5 m^2. This limited home range could have been because of drought conditions, but other studies have also shown limited movements in summer habitat with *A. maculatum* staying in the same location for several weeks (Madison 1997). However, one study of non-breeding habitat of *A. maculatum* estimated a home range of 16–20 m^2 with frequent movements (Faccio 2003). *Ambystoma talpoideum* has been shown to have a variable home range (0.11–23.2 m^2) and variable amounts of daily movement also (Semlitsch 1981).

The results of this study show that PIT tags and new multidirectional RFID antenna technology can be a useful tool for tracking and individual identification of *Ambystoma* species during fossorial periods of their yearly activity cycle. Because of the exceptional drought conditions present during this study (NOAA 2008) we feel that future work may yield higher recapture rates of marked individuals. PIT tags allow for individual identification, have a lifespan of at least 10 years, are relatively affordable, can be detected up to 27.5 cm below the soil surface, have a linear accuracy equivalent to other methods, and have the potential for increased relative distance and depth detection based on further improvements in antenna technology.

Acknowledgments.—We thank Virginia Highlands Community College (VHCC) General Biology students 2006–2007, S. Bobo (VHCC), M. Snead (VHCC), and C. Akers (VHCC), for their assistance in the field. This study was partially funded by the State of Virginia Tech Prep Initiative, Virginia Community College System National Science Foundation Grant (DUE 0402567), East Tennessee State University RDC grant #06-026 (TFL) and the Tennessee Wildlife Resources Agency. The procedures used in this study were approved by the ETSU animal care and use committee (P070902) and the Tennessee Wildlife Resource Agency (collection permits 1888, 1986). We thank two reviewers for comments on a previous draft which greatly improved this manuscript.

Comparison of Two Diet Collection Methods in the Lizards, *Sceloporus jarrovii* and *Sceloporus virgatus*

The diet of the Striped Plateau Lizard (*Sceloporus virgatus)* has been described as insectivorous (Cole 1963; Smith 1996, 1999), although a conclusive diet analysis has not been done. Several experimental studies have shown the lizard's willingness to eat mealworms (*Tenebrio*), crickets (*Acheta*), and acridid grasshoppers in both laboratory and field-based feeding experiments (Ballinger and Holscher 1983; Phelan and Niessen 1989; Weiss 2001). A stomach content analysis on individuals from Sonora, Mexico showed a high percentage of the diet composed of Hymenoptera (ant: 52%, non-ant: 18%) and adult Coleoptera (14%) (G. R. Smith, unpubl. data). Smith (1999) noted anecdotally that *S. virgatus* has also been observed attempting to eat a centipede (30–40 mm in length).

The diet of the Yarrow's Spiny Lizard (*Sceloporus jarrovii*) is much more extensively known than that for *S. virgatus*. *Sceloporus jarrovii* feeds on a wide variety of insects, spiders, and plant matter. Stomach content analyses have shown that adults eat more Coleoptera, large Heteroptera (formerly Homoptera), and Lepidoptera, whereas neonates feed predominantly on small Heteroptera and Hymenoptera (ants). Both age classes eat approximately equal amounts of Orthoptera, Heteroptera (formerly Hemiptera), Diptera, Hymenoptera, and Arachnida (Bursey and Goldberg 1993). In a separate study, Barbault et al. (1985) observed that the bulk of adult stomach contents were made up of Coleoptera, Orthoptera, and Lepidoptera. There were also observed differences in the size of prey items present between neonates and adults; however, it has been suggested that this could result from differences in gape size and microhabitat use (Bursey and Goldberg 1993). These differences in prey size captures may help to reduce competition among different ages and sizes of *S. jarrovii* (Simon 1976).

A diet analysis based on behavioral observations has not been completed on either *S. virgatus* or *S. jarrovii*. All previous diet studies of *S. jarrovii* have been conducted by stomach content analysis via dissection (Ballinger and Ballinger 1979; Barbault et al. 1985; Bursey and Goldberg 1993; Goldberg and Bursey 1990; Simon 1975, 1976; Simon and Middendorf 1985). Diet studies of *S. virgatus* have not been completed by any method. Diet analysis of other *Sceloporus* species have also only been completed using stomach contents (Barbault et al. 1985; Ballinger et al. 1977; Rose 1976). In order to test the validity of determining diet through behavioral observations, I compared prey selection in observations with stomach contents as part of a long-term study of foraging behavior.

Methods

The foraging study was conducted at two sites (Herb Martyr and John Hands Campgrounds) near the American Museum of Natural History's Southwestern Research Station (SWRS), located outside Portal, Arizona (USA) inside the Coronado National Forest of the Chiricahua Mountains from May to July in 2004 and 2005. Both sites are located in seasonally dry creek beds adjacent to two USDA Forest Service Campgrounds a few miles from SWRS and have ample sympatric populations of both *S. jarrovii* and *S. virgatus*.

The Herb Martyr (HM) site was located at 31.8724167°N, 109.2352667°W (elev. 1787 m). This study area was 200 m long and spanned the width of the creek bed (3–7 m) and ca. 7 m on each side of the creek bank. The transect was demarcated at the northwest end by a barbed wire fence, delineating the end of the campground property, and on the southeast end by a dam. The John Hands (JH) study area was 320 m in length and was located at 31.8782333°N, 109.22295°W (elev. 1714 m). The site was bordered by a 0.5 m tall concrete dam at the top and a 5 m tall dam at the lower end. The width of the creek bed varied between 10 and 15 m, and up to 20 m of creek bed bank was also used. Within the first few weeks of the study, the creek beds located at both sites were dry, with no water flowing. Both sites had an upper canopy primarily of Alligator Juniper (*Juniperus deppeana*), Arizona Sycamore (*Platanus wrightii*), and Ponderosa Pine (*Pinus ponderosa*), with an understory of willow (*Salix* sp.), *Yucca* sp., and seedlings of the larger trees.

Behavioral Assays.—During the first week of research in both 2004 and 2005, up to 30 individuals of each age class and species at both sites were caught by handheld nooses. Captured lizards were identified to species, sexed, and placed into an age category (neonate or adult). Neonate and adult *S. jarrovii* were easily distinguishable based on size because the neonates were less than half the size of the adults. Lizards were individually marked using toe clips (Tinkle 1967) and paint markers (Jones and Ferguson 1980; Simon and Bissinger 1983) and then released.

Feeding behavioral assays were then conducted May to July. Lizards were observed daily from 0830 h to 1200 h, and often from 1400 h to 1600 h, in half-hour increments. Observations were conducted from at least a 1 m distance to avoid disturbing the lizards. I recorded the size and type (description and taxonomic classification) of prey captured. A total of 106 *S. jarrovii* adult, 70 *S. jarrovii* neonate, and 73 *S. virgatus* adult successful foraging observations were made. At least one observation was made per marked lizard, and in some cases, up to four observations were made per lizard.

Stomach Content Collection.—Stomach flushes, using the methods of Legler (1977), Legler and Sullivan (1979), and James (1990), were performed on ten unmarked lizards of each group (*S. jarrovii* adults, *S. jarrovii* neonates, and *S. virgatus* adults) at each site to compare behavioral observations of prey choice with stomach content analysis. Lizards captured for stomach flushing were collected in creek beds, upstream and downstream of the boundaries of each site to avoid disrupting the study populations. All lizards were collected between 1100 h and 1200 h and returned to the sites by 1700 h the same day. Stomach flushing was done in a laboratory at the Southwestern Research Station.

Stomach contents were collected using the following method. The lizard's mouth was propped open using a stiff plastic ring. Then a thin catheter (inner diameter = 1.19 mm, outer diameter = 1.70 mm) was passed down the esophagus until reaching the end of the stomach, as felt by external palpation (Legler and Sullivan 1979). To further reduce the risk of over-insertion, the length of the tube was measured against the outside of the lizard body to just before the forelimbs, which corresponds to the midpoint of the stomach (James 1990). Once the tube was inserted it was connected to a 10cc hypodermic syringe and enough room-temperature water was pumped into the stomach to enable the food to rise to the mouth. Early trials suggested that cold water was more likely to put the lizard into shock during stomach flushing. Food was removed either by forceps or by suspending the lizard upside-down over a fine mesh net to let the items flow out with the water (James 1990; Legler 1977; Legler and Sullivan 1979). While the stomach was full of water, the abdomen was gently massaged to break up the food bolus (Middendorf 2005). This entire flushing process was repeated until no food came out of the stomach (2–4 times total).

After stomach flushing completion, the lizards were held in small plastic terraria and monitored for any adverse effects for at least one hour. If the lizard stopped breathing after the procedure was completed, it was briefly immersed in a bucket of ice water to "jump-start" its system (James 1990). Any lizards that did not survive the procedure were dissected to determine cause of death and any residual stomach contents were removed and preserved (N = 18). These contents were combined with the prey items obtained through stomach flushing for analysis.

All food items were collected in a fine mesh net, transferred to a 45 ml sample vial, and stored in 75% ethanol until analysis in Fall 2005. Stomach contents were sorted and identified to the lowest classification level possible, usually to the Order level (Bland and Jaques 1978; Jackman 1997; Milne and Milne 1980; Roth 1985). The abundance of prey items was identified by counting the number of complete organisms or by using the number of heads, legs, or wings to estimate total number of items eaten of each prey type.

Results

Diet content in 2004 and 2005 foraging assays differed from that of stomach content analysis (Table 1). The predominantly observed prey types for *S. jarrovii* adults were Formicidae (2004: 27%, 2005: 63%), Diptera (24%, 23%), and Isoptera (44%, 2004 only). In contrast, the stomach contents for this lizard group primarily consisted of Formicidae (55%) and Hymenoptera (16%). The stomach contents contained several taxa that were never observed in the behavioral observations: Hymenoptera (as stated previously), Arachnida (3%) and Heteroptera (8%). Also, the high prevalence of Diptera in the observed diet was not confirmed by stomach content analysis, as Diptera were not present in any stomachs of *S. jarrovii* (Table 1).

Neonates of *S. jarrovii* showed similar differences in diet based on the source of the data. The dominant prey taxa in behavioral assays were Formicidae (2004: 27%, 2005: 77%) and Diptera (2004: 62%, 2005: 16%). Diptera were not found in any neonate stomachs and the most prominent prey types were Formicidae (38%) and Heteroptera (35%), a taxon not observed in the foraging assays. Several additional taxa found in the stomach contents, but lacking in the behavioral data were Arachnida (6%), Hymenoptera (non-ant; 6%), Scorpiones (1%), Isopoda (3%), and unidentifiable fleshy larvae (4%) (Table 1).

Diet comparisons of stomach contents and behavioral observations for *S. virgatus* revealed similar differences to both adult and neonate *S. jarrovii*. The dominant prey items from behavioral observations were again Formicidae (2004: 54%, 2005: 52%) and Diptera (2004: 34%, 2005: 31%). Dipterans were notably absent from stomach contents. The dominant food items found in the stomachs were: Formicidae (36%), Heteroptera (19%), and Coleoptera (23%). Heteroptera was not present in the behavioral diet and Coleoptera were only present in small amounts in 2005 (5%). Arachnida were not present in the behavioral diet, but made up 8% of the stomach content diet (Table 1).

Discussion

Observations of prey attacked revealed that the dominant food items in the diet of adult *S. jarrovii* were Formicidae, Diptera, and Isoptera (Table 1). This contrasts somewhat with the stomach content diet, which consisted predominantly of Formicidae and Hymenoptera (non-ant) (Table 1). Previous stomach content analyses have shown that the adult *S. jarrovii* eat mainly Coleoptera, Heteroptera, Lepidoptera, and Orthoptera (Barbault et al. 1985; Bursey and Goldberg 1993). Differences in dominant food items between this study and previous work may be due to the differences in study locations, which undoubtedly have differing available prey bases. The Bursey and Goldberg (1993) study occurred in Pima Co., Arizona (southwest of Tucson) and the Barbault et al. (1985) study occurred in northern Mexico, whereas this study was limited to the early summer in the Chiricahua Mountains (southeast of Tucson). In addition, the high incidence of Isoptera in the observational diet was an isolated incident in 2004. A single individual that I was observing found a hole in the ground from which reproductive termites were emerging, enabling the lizard to eat a large number of termites (32) with very little effort.

For neonate *S. jarrovii*, the diet was very similar to adult *S. jarrovii* in that it was dominated by Formicidae and Diptera in the behavioral observation diet (Table 1). The stomach content diet was high in Formicidae, but also Heteroptera (Table 1). For *S. virgatus* the dominant prey items in the observational diet are Formicidae and Diptera, similar to both age classes of *S. jarrovii* (Table 1). The stomach contents, however, are made up mainly Formicidae, Heteroptera, and Coleoptera (Table 1).

Observed diet analysis discrepancies may be an artifact of the methodology surrounding stomach content analysis in general. The stomach flushing technique may not be as exhaustive as dissection, as some prey items may not be successfully removed from the lizard's stomachs. It is possible that the items least likely to be removed were large-bodied organisms that could not be washed out by water. Of the 18 individuals (3 *S. jarrovii* adults, 11 *S. jarrovii* neonates, and 4 *S. virgatus*) that died during the procedure and were later dissected, only one individual (an adult *S. virgatus*) had a completely empty stomach, so it appears that this method did not disgorge all items. Although not all prey items were extracted from the stomachs, those items that were extracted

are still useful for comparison with the behavioral observations.

A second explanation for the diet discrepancy is that many prey items may have been partially digested due to the length of time since eating, resulting in an underestimate of easily digested organisms (Vitt and Zani 1998). All of the lizards in this study were kept for a minimum of two hours before stomach flushing. Lepidopterans, which are known to be dominant in the diet of adult *S. jarrovii* (Barbault et al. 1985; Bursey and Goldberg 1993), were not present in high numbers in the stomach samples (Table 1), possibly because these soft-bodied organisms are digested fairly quickly (Bullock et al. 1993). The only evidence of Lepidoptera in the stomach contents were wings, which I counted to get an estimate of the number of individuals eaten. This technique may have resulted in an underestimate of the number of Lepidoptera present in the diet, though behavioral observations were consistent with this low prevalence (Table 1). Perhaps completing stomach flushes immediately upon capture would alleviate some of these issues, however, it still does not resolve the problem of lizards that have been foraging for hours prior to capture.

Diptera were a major dietary component for all three lizard groups according to the behavioral observations, but were not present in any of the stomach contents (Table 1). Diptera are soft-bodied, with very little chitin, making them an easily digested prey source. However, unlike the Lepidoptera, there was no evidence of Diptera wings or other identifiable body parts in the stomach contents. Unpublished data of *S. virgatus* stomach contents also show no evidence of Diptera eaten, though "unidentifiable" organisms made up 9% of the diet and perhaps partially digested Diptera were contained therein (G. R. Smith, unpubl. data). Another alternative is that no Diptera were actually ingested, although this conflicts with the behavioral observations, and seems very unlikely due to heavy prevalence of Diptera at the site (pers. obs.).

The contradiction between the diet sources within this study may also be an artifact of observer bias. Since behavioral observations occurred at a distance of over one meter, and often over two meters, it is entirely possible that what the observers thought was a "fly" may simply have been another small flying insect that could not be distinguished at that distance. This bias may also explain why Heteroptera and Hymenoptera were either rare or completely lacking in the observational diet of all three lizards groups, yet are common in the stomach contents of this study (Table 1) and other previous studies (Bursey and Goldberg 1993). However, I am confident that the behavioral methodology was sound and may need only further refinement to improve accuracy.

While both the stomach flushing method and behavioral observations provide valuable insight into the diet of *S. jarrovii* and *S. virgatus*, it is unclear which method is truly representative of their diets. Likely, both methods are only pieces of the whole picture, but by looking at the data from both methods together, we gain a much greater understanding of the diet of these two lizard species. Further research comparing behavioral observations and stomach contents will need to be conducted in order to determine if an observational method alone can be used as a representation of lizard diet. This experiment is also the first time that this particular behavioral methodology has been used, so repetition of

TABLE 1. Total diet composition from stomach contents and behavioral observations. Data for each prey item are represented as the percentage of the entire diet from that source.

Lizard Group	Data Source	N	Arachnida	Chilapoda	Coleoptera	Diptera	Formicidae	Heteroptera	Hymenoptera	Isoptera	Lepidoptera adult	Orthoptera	Scorpiones	Unidentified larvae
Sceloporus jarrovii adult	stomach	20	3.3	0.7	9.8	0	54.9	8.5	15.7	0	3.3	0	0	2.6
	behavior 04	76	0	0	0	24.7	27.3	0	0	44.2	0	0	0	1.3
	behavior 05	30	0	0	6.7	23.3	63.3	0	0	0	6.7	0	0	0
Sceloporus jarrovii neonate	stomach	20	6.1	0	6.1	0	37.8	35.0	5.6	0	1.7	0	1.1	3.9
	behavior 04	27	0	0	0	61.5	26.9	0	0	7.7	3.9	0	0	0
	behavior 05	43	0	0	7.0	16.3	76.7	0	0	0	0	0	0	0
Sceloporus virgatus adult	stomach	20	8.8	0	23.4	0	35.8	19.0	4.4	0	5.8	0	0	2.9
	behavior 04	38	0	0	0	34.3	54.3	0	0	0	2.9	2.	0	2.9
	behavior 05	35	0	0	5.6	30.6	52.8	0	2.8	0	0	5.6	0	2.8

the methodology may be necessary. Other than keeping lizards in enclosures and feeding them all possible prey items, the two methods in this study are our best hope of determining lizard diets while providing minimum impact. In addition, it is important to develop a method to determine diet through behavioral observations, since this is the only method by which we can also record prey species-specific data on pursuit time, search time, handling time, or prey capture success rate in the field.

Acknowledgments.—I thank my advisory committee at the University of New Hampshire (UNH): James T. Taylor, Michelle P. Scott, and Kimberley J. Babbitt. Thanks also to the following people for their help and support in reviewing this manuscript: John Iverson, Geoff Smith, Samantha Larimer, Erica Westerman, and Liam Kean. I also thank Kater Atkinson, Morgan Eastman, and Katie Maslack for their assistance in stomach content analysis, conducted at UNH. I would also like to thank the staff of the Southwestern Research Station (SWRS). While at SWRS, I had the opportunity to work as a volunteer to defray the cost of room, board, and use of laboratory facilities. Other volunteers at the station worked as field assistants: Patrick Oakes, Courtney Rudd, Alyson Gould, Oliver Nicholls, Amanda Dickson, Heidi Camp, Deanna Morrell, Amy Windsor, Nicola White, Giles Manning, Gemma Wiacek, Alexandria Sebastien, Susanne Donandt, and Jeff Nelson. I also received funding from the SWRS Student Support Fund to pay my room and board costs for two weeks of research in 2005. Other sources of funding included the American Society of Ichthyologists and Herpetologists Gaige Fund for Herpetology, received in May 2005. I was granted permission for animal research by UNH's IACUC committee on 12/03/03 (#031102) for lizard measurements and marking. On 12/15/04 (#041105), permission was also granted for stomach flushing of lizards. I received scientific collection permits from the State of Arizona's Game and Fish Commission in both 2004 (SP806594) and 2005 (SP634747). I also received permission from the Southwestern Research Station to conduct research in the Coronado National Forest.

Large snake species are important predators in their ecosystems (Dodd 1987; Greene 1997; Lawson and Klemens 2001). Rhinoceros Vipers (Viperidae: *Bitis rhinoceros*, Schlegel, 1855) are among the biggest and most massive venomous snakes (Phelps 1981). Taxonomically they are closely related to the Gaboon Viper, *Bitis gabonica* (Duméril et al. 1854), and were long considered to be only a subspecies of the latter. A sister species to these two taxa is the Nose-horned Viper, *Bitis nasicornis* (Calvete et al.

2007; Lenk et al. 1999; Lenk et al. 2001). Although there is no ecological study on the Rhinoceros Viper, they are likely to have a very similar ecological niche to the Gaboon Viper. Therefore, we herein compare our data to *B. gabonica*. *Bitis rhinoceros* occurs in Western Africa from Guinea to Togo (e.g., see Chippaux 2001), while *B. gabonica* ranges from Nigeria to central, eastern, and southern Africa (e.g., see Spawls and Branch 1995).

These two vipers can reach 1.80 m (Chippaux 2001; FitzSimons 1962; Pitman 1974; Spawls and Branch 1995) and weigh up to 10 kg (Greene 1997). Their size and strong venom enable them to kill and feed on a wide variety of prey, including medium-sized mammals (Bodbijl 1994; FitzSimons 1962; Luiselli 2006b; Mallow et al. 2003; Marsh and Whaler 1984; Perrin and Bodbijl 2001; Pitman 1974; Spawls and Branch 1995). Both viper species may be very abundant in some habitats (Ionides and Pitman 1965, Luiselli and Akani 1998; Rödel and Mahsberg 2000); for example, Lawson (1993) documented especially high densities of *B. gabonica* in altered habitats like farms and plantations in Cameroon. In Côte d'Ivoire, Doucet (1963) found 282 *B. rhinoceros* on only a few km^2. This indicates that these large forest vipers might play an important functional role in their ecosystems. Unfortunately, knowledge about abundances and ecology of this species is rather anecdotal and stems mostly from extrapolations of *B. gabonica*. In general, there are little data on the ecological role of huge vipers (Greene 1997; Schuett et al. 2002).

Because of their camouflage coloration combined with a sit and wait hunting strategy, it is very time intensive to ascertain the presence of these snakes (even when radio-tracked, Lawson 2006) and almost impossible to estimate exact abundances (see Kéry 2002). There are no studies that investigated the ecology of *B. rhinoceros* and few on *B. gabonica*. Research on *B. gabonica* was conducted in outdoor enclosures (Akester 1979; 1989) and in the wild. The latter was done by applying radio-tracking (Angelici et al. 2000; Bodbijl 1994; Perrin and Bodbijl 2001a; Lawson 2006; Linn et al. 2006) and visual encounter surveys (Luiselli and Akani 1998, 2003; Luiselli et al. 1998; Luiselli 2006a, b; Perrin and Bodbijl 2001b). Numbers of snakes studied varied strongly between studies but were mostly low, ranging from two (Lawson 2006), four (Angelici et al. 2000), six (Linn et al. 2006) to nine (Bodbijl 1994; Luiselli and Akani 1998; Luiselli et al. 1998; Perrin and Bodbijl 2001a) individuals. Numbers increased to 57 (Perrin and Bodbijl 2001a), 81 (Luiselli 2006a), 97 (Perrin and Bodbijl 2001b), 524 (Luiselli and Akani 2003) and 586 (Luiselli 2006b) when i) search effort was strongly elevated (e.g., through high manpower, visiting bush meat markets), ii) secondary habitats were searched, and/or iii) data were pooled over several years, sites, habitats, or supplemented with museum specimens.

In addition to the difficulty of detecting large forest vipers, they are also dangerous and difficult to handle. They have the longest fangs of all snakes (Pough and Groves 1983) and their large venom glands (Grasset 1946; Pezzano 1986) produce a huge amount of highly haemotoxic venom (Brown 1973; Broadley et al. 2003; Chippaux 2002; Grasset 1946; Phelps 1981; Wildi et al. 2001). Most untreated bites probably are fatal (Chippaux 2002; Mallow et al. 2003; Marsh and Whaler 1984; Marsh et al. 1997, 2007; Spawls and Branch 1995). Though these snakes are considered to be of a docile nature (e.g., Angelici et al. 2000; Broadley et al. 2003; Isenmonger 1962; Lawson 2006; Wildi et al. 2001),

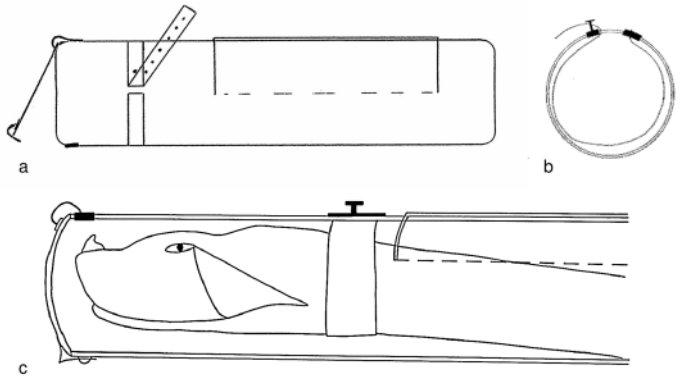

FIG. 1. Transparent Plexiglas tube used for handling Rhinoceros Vipers. a) and c) illustrate how the left side can be closed. The leather belt to fix the snakes' head was attached with a screw on the outside of the tube. a) View of the whole tube, indicating the window that can be opened on the tube's side. b) Cross section of the tube, illustrating the attachment of the belt. c) The belt should be fastened around the neck of the snake.

handling *Bitis* species poses a severe danger to researchers. This is an important point because medical services in many areas in Africa are generally not well prepared for dealing with snake bite victims (Chippaux 1998; Chippaux 2005; Theakston and Warrell 2000; Theakston et al. 2003; Stock et al. 2007). Additionally, many research areas are too remote to reach proper medical services within an acceptable time span. Hence the personal risk while investigating these snakes has to be minimised.

In order to investigate the role and importance of these large predators in an undisturbed West African rainforest, we tested a new method of finding Rhinoceros vipers and developed a new secure handling method.

Study site.—Our study site was situated in the Taï National Park, which is located in the southwest of Côte d'Ivoire (5°08'–6°07'N, 6°47'–7°25'W), close to the southeastern border of Liberia. It is one of the largest remaining blocks of the Upper Guinean rainforest (Vooren and Sayer 1992). The study area comprised roughly 770 ha of natural forest around the "Station de Recherche en Ecologie Tropicale" (SRET; 5°50'03"N, 7°20'536"W), maintained by the University of Abobo-Adjamé, Abidjan. Rainfall around the SRET is ca. 1800 mm annually, with peaks from March to July and from September to December (Rödel and Mahsberg 2000).

Methods.—Because of their cryptic coloration and secretive lifestyle it is very difficult to record Rhinoceros Vipers with methods like visual encounter surveys on transects, plots, or random searches in particular habitats. Other methods such as cover boards, artificial dens, or different kinds of traps are not applicable for this species, possibly because of their assumed high underground activity, as observed in Nigeria (Angelici et al. 2000) but not confirmed for South Africa (Linn et al 2006; Perrin and Bodbijl 2001a), and presumed low daily movement rates (Alexander and Marais 2007; Linn et al. 2006; Mallow et al. 2003). Previous studies suggest that *B. gabonica* relies rather on its cryptic camouflage than on shelters (Lawson 2006; Linn et al. 2006; Perrin and Bodbijl 2001a; Pitman 1974). Hence these methods could yield few vipers but not in a reliable manner.

The new method for tracking forest vipers we developed employs following monkeys habituated to humans, Sooty

Mangabeys (*Cercocebus torquatus atys*). During the day, these monkeys forage about 80% of the time on the ground (Berggmüller 1998; Rutte 1998). When encountering a snake, they usually seem to ignore it. However, snakes of the genus *Bitis* are treated differently. The monkeys jump aside and give loud, distinct alarm calls (Range and Fischer 2004), which attracts other monkeys to the site, facing the snake and giving alarm calls as well. In the Taï Monkey Project a habituated mangabey group was followed on a daily basis (Range and Noe 2002). This group consisted of 100–120 individuals of all age classes. Researchers and field assistants followed the monkeys and marked all places with flagging tape where vipers had been indicated. Subsequently, we located the snakes and took the geographic position of these places and photographs of the snake's heads. The latter were used to ascertain individual identification (see Ferner 2007). To assure long-term identification some snakes were additionally marked with a PIT tag (Passive Integrated Transponder; Trovan©) injected subcutaneously, laterally in front of the tail on the right side of the body. For that purpose we had to capture and handle the snakes.

For handling the vipers safely we used custom-made transparent Plexiglas tubes (wall of the tubes 3–4 mm thick) which were open at one end and lockable on the other. Close to the lockable end a loop of leather belt was fed into the pipe. The leather belt was fixed to the outside of the tube in one position and slides through a slot with a locking mechanism in the other (Fig. 1). We had six different sizes of tubes (diameters ranging from 5 to 30 cm; length ranging from 50 to 100 cm), which enabled us to handle various sizes of vipers. If the snake was covered with leaves and/or wood, the cover was first removed. The snake was then gently lifted or pushed into an open area with a long hook (1.80 m) and the head subsequently pinned to the ground using the same hook. The open end of the tube was then placed over the snake's head by a second person. Either the snake started crawling further into the pipe on its own or was still pinned down by the first person, while the second was pushing the tube further ahead. When the head finally passed through the leather belt, the belt was pulled and fixed on the outside of the tube. Due to the triangular head shape, the snake subsequently was not able to move backwards, even when the belt was not too tight. A very tight belt has to be prevented in order to avoid strangulation and because it is suggested that the common procedure of gripping heavy-bodied venomous snakes (e.g., *Lachesis muta*) by their necks can cause serious injuries to the snakes (Ripa 2002). A removable lid on the side of the tube allowed us close examination of the snake's body for detection of ectoparasites, counting scales, inserting PIT tags, etc. (see Fig. 1). After recording data (e.g., pattern, length, weight) the belt was loosened and the tube slowly lifted. The person holding the hook followed the movement of the tube so that the part of the snake outside the tube was always pinned until the head could be reached with the hook. The person holding the tube retreated and the hook was removed afterwards.

Results.—The handling method proved to be effective and safe. No snake under restraint got out of the tube (N = 5). However, the belt had to be fixed at the locking mechanism because some snakes tried to squeeze themselves backwards through the belt. It was also necessary that one person was always holding the hind part of the snake's body in order to prevent the snake from turning around. Both implementations are necessary because due to the large girth, the small neck and the ability of changing the girth dramatically by moving ribs or inflating, no tube will prevent efforts of squeezing around the own axis backwards without injuring the skin. Afterwards these lesions might become entry points for parasites, infections, etc.

Sooty Mangabeys were followed during 429 days (3110 observation hours) from October 2001 to September 2002. We recorded a total of 43 Rhinoceros Vipers (0.01 snake/h). Two snakes were encountered twice. The 41 individuals were registered in an area of 770 ha (1 snake / 18.8 ha). Viper locations were randomly spaced (Nearest Neighbor Analysis R = 0.75, Donnelly Modification for Clark and Evans Test z = -3.44) within the mangabeys' home range (770 ha). Most Rhinoceros Vipers were found between 1000 h and 1400 h (28 snakes). A seasonal peak was registered in October 2001 (12 snakes). During a parallel study on leaf litter anurans (Ernst and Rödel 2005; Rödel and Ernst 2004), we employed 382.5 h of transect walks, thereby carefully investigating the forest floor. During this time, we recorded one Rhinoceros Viper (0.002 snake/h). During additional random visual encounter surveys for litter frogs (without accompanying monkeys, 1999–2002; total time not recorded), we found two more vipers. Unfortunately, we had to interrupt all studies in October 2002 due to the start of a civil war.

Discussion.—To our knowledge our capture protocol is the safest method for the human observer and large vipers alike. The tubes prevent snakes from breaking free through violent and sudden head jerking as has been observed in other vipers, e.g., *Bitis arietans* (Visser and Chapman 1980). The tubes are easily fabricated and can be customized to any size and modified for specific needs, such as the removable window on the side of the tube which we employed for the insertion of PIT tags (Lang 1992).

Although the monkeys clearly showed fear of big vipers, the respective reasons remained unclear and were not addressed in our study. It is long known that various species of monkeys react with specific alarm calls ("conceptual semantics") towards snakes (Coss et al. 2007; Crockford and Boesch 2003; Fichtel et al. 2005; Range and Fischer 2004; Struhsaker 1967; Seyfarth et al. 1980a, b), especially if the snakes are moving. However, we observed that they react towards stationary snakes and that reactions towards Rhinoceros Vipers (and Nose-Horned vipers, *Bitis nasicornis*) differ from those toward other snakes such as Forest Cobras (*Naja melanoleuca*). This is contrary to observations on Vervet Monkeys (*Chlorocebus aethiops*), where monkeys reacted with specific alarm calls towards Puff Adders (*Bitis arietans*) and Egyptian Cobras (*Naja haje*) (Struhsaker 1967). We hypothesize that large vipers are capable of killing and subsequently devouring such large prey (Angelici et al. 2000). Large prey items are rare (Luiselli and Akani 2003; Luiselli 2006b; Perrin and Bodbijl 2001b), but a Royal Antelope (*Neotragus pygmaeus*) has been recorded for *B. rhinoceros* (Cansdale 1965). A Large Spotted Genet (*Genetta tigrina*) (Perrin and Bodbijl 2001b) and monkeys (Broadley and Cock 1975; *Chlorocebus pygerythrus*, J. Newby quoted in Broadley et al. 2003) have been noted for *B. gabonica*. We never observed any encounters with Rock Pythons (*Python sebae*), which do occur in the area and elicit alarm calls in three other monkey species (Starin and Burghardt 1992) and are easily capable of feeding on Sooty Mangabeys (e.g., see Cowlishaw

1994; Starin and Burghardt 1992; Struhsaker 1967). Other snakes, although capable of killing monkeys with their venom (*Naja* spp.), are smaller and their gape limitation does not allow them to feed on monkeys. An additional hypothesis assumes that the monkeys warn other members of their group when encountering vipers (Cheney and Seyfarth 1992; Struhsaker 1967) to not accidentally step on the snake, thereby avoiding a defensive bite. Neither of the two viper species will flee immediately when detected by a group of mangabeys, allowing the behavior of habituated mangabeys to be exploited to locate large forest vipers.

The peaks of snake records between 1000 h and 1400 h were most likely due to peaks in foraging activity of the monkeys during that same time period. Similarly, a seasonal peak of snake records was coincidental with fruiting (October–December and May–June) of one major fruit tree used by the mangabeys (*Saccoglottis* sp.). During these periods the monkeys covered a larger foraging area than during other periods, therefore increasing the chance to encounter more snakes. The observed density of 0.053 snakes per hectare is at the lower limit known for comparable sized species (see review by Parker and Plummer 1987) and lower than modelled densities of the sister species *B. gabonica* in southern Nigeria (mean: 0.22/ha; min.: 0.014/ha; max.: 0.372/ha; Luiselli 2006a). However, we would have needed a much higher recapture rate to calculate real densities. The monkeys did not equally use all parts of their home range and although a Nearest Neighbor Analysis of the Rhinoceros Viper records revealed a random distribution in the forest, we cannot exclude the possibility that the snakes could be much more abundant in parts were monkeys forage rarely.

Our results showed that, by using the monkey's specific warning system, we have identified a highly valuable method to detect large vipers in West Africa. Data from our study revealed more vipers per unit time compared to visual encounter surveys. Our refined method of tubing snakes is highly recommended for safe handling of large vipers.

Acknowledgments.—We thank Karline Janmaat, Richard Pého, Gérard Gha, Georges Gnonli Gbamlin, and Céléstin Koui for providing invaluable help in the field. Norbert Schneider constructed the Plexiglas tubes. The SRET provided permits and housing. Research and access permission was given by the Ministère de l'Enseignement Supérieur et de la Recherche Scientifique, and the Ministère de la Construction et de l'Environnement of the Republic of Côte d'Ivoire. Field work of JP was supported by the Fonds Internationale Hochschule of the University of Würzburg, FR by the DAAD Doktorandenstipendium im Rahmen des gemeinsamen Hochschulsonderprogramms III von Bund und Ländern. This study complies with the "Guidelines for the Use of Live Amphibians and Reptiles in Field and Laboratory Research" jointly published by the ASIH, HL, and SSAR. The manuscript benefited from comments from Luca Luiselli and an anonymous reviewer.

The amphibian fungal disease chytridiomycosis caused by *Batrachochytrium dendrobatidis* (*Bd*) has been found in several parts of the world including Africa, Australia, Europe, Central, South, and North America (e.g., Berger et al. 1998; Skerratt et al. 2007), yet its geographic distribution is not fully known. Based on current patterns, the great majority of species and populations that have been affected have occurred in montane habitats or areas characterized by relatively moist climates (Stuart et al. 2004; Longcore et al. 2007). In North America, *Bd* has been reported from numerous species, with the earliest recorded incidence of infection dating back to 1961 (Ouellet et al. 2005; Longcore et al. 2007; AmphibiaWeb 2007). *Bd* is recorded from latitudes as far north as Alaska, USA (e.g., Adams et al. 2007; Reeves 2008), and at elevations extending from near sea-level at Point Reyes, California, USA, to 3550 m in the Sierra Nevada, California (Fellers et al. 2001; Morgan et al. 2007; Spatialepidemiology.net 2008).

Recently, *Bd* has been confirmed in native, desert frog species *Lithobates* [=*Rana*] *yavapaiensis*, *L. chircahuensis*, *L. tarahumarae* and *Hyla arenicolor* in Arizona (Bradley et al. 2002; Hale et al. 2005) and is hypothesized to be a key factor in the extirpation of populations of these species. Locally in southern California, *Bd* is known to occur in the native species *Anaxyrus* [=*Bufo*] *californicus* (Mendelsohn et al. 2005), and *Rana draytonii* (Ervin et al. 2001). Individuals from established populations of the introduced frog species *L. catesbeianus* and *L. berlandieri* in the southwestern United States have been reported to be infected with *Bd* (Sredl 2002). Consequently, the concern now is that infected individuals from these populations, and other undiagnosed populations, may serve as vectors for *Bd* to naïve populations of native frogs (Hanselmann et al. 2004, Sredl et al. 2002). *Lithobates berlandieri* is native to Texas and New Mexico but has been introduced to Arizona and California within the last 35 years (Rorabaugh et al. 2002).

On 23 January 23 2007, one of us (BC) collected a dead *L. berlandieri* in Coachella Valley, California, USA (33.5352722°N, 115.9883278°W), south of the town of Mecca, and ~1 km N of the Salton Sea. The animal was found in an agricultural ditch (~2 × 35 m) filled with 5– 20 cm of standing water and with lush emergent vegetation and a dense mat of green algae, at –58 m below sea level. The specimen was photo documented (LACM PC1457–1460), and examination revealed bright red coloration on the ventral surface of the legs that is uncharacteristic of the natural coloration for this species. Museum acronyms used follow Leviton et al. (1985). Subsequent searches of the area were made, and on 13 March 2007 one of us (MJR) collected an additional living specimen from the same agricultural ditch. Upon capture the frog was moribund and unable to right itself when placed on its back. The ventral surfaces of its legs were reddened similar to the frog that was found dead. The second frog perished within a day of capture, despite efforts to maintain it in captivity until it could be prepared as a museum specimen. It was preserved in 95% ethanol and a complete necropsy was performed on the fixed carcass. Sections of the dorsal and ventral skin, heart, lung, liver, kidney, pancreas, tongue, stomach, small and large intestine, brain, eye, skeletal muscle, bone, and bone marrow were post-fixed in 10% neutral buffered formalin and processed routinely for histology. When hematoxylin- and eosin-stained sections were examined by light microscopy, lesions were limited to the skin and other tissues were histologically normal. Histologic findings included: near diffuse mild to moderate epidermal hyperplasia with multifocal epidermal erosion; scattered single cell necrosis of keratinocytes; moderate to marked congestion of dermal capillaries: and a mild multifocal lymphohistiocytic dermatitis. Occasionally, within the superficial keratin layers (*stratum corneum*) there were small numbers of spherical fungal thalli with evidence of internal septation (colonial thalli) morphologically typical of *Bd* (Berger et al. 2005; Longcore et al. 1999). Based on these findings, death was attributed to chytridiomycosis. A swab obtained from the skin was processed following previously described methods for a Taqman® polymerase chain reaction (PCR) assay to detect *Bd* DNA (Boyle et al. 2004; Hyatt et al. 2007). PCR results were positive, confirming the morphologic identification of *Bd* on histologic examination. The frog is vouchered as SDSNH 72858.

This observation of *Bd* infection is notable for several reasons. First, it represents the first record of *Bd* in *L. berlandieri* in California. *Lithobates berlandieri* is expanding its range in the deserts of the American southwest (Rorabaugh et al. 2002), and also occurs in sympatry with other native aquatic amphibian species such as *Anaxyrus punctatus, A. woodhousei*, and *A. alvarius*, *Pseudacris hypochondriaca* (pers. obs.). The determination that *Bd* is now known to occur in this region highlights the need for other local native species to be monitored to investigate the impacts of this pathogen in a region otherwise characterized by extreme heat and low humidity. Second, this is the first incidence of

Bd below sea level in one of the hottest and driest locations in the western hemisphere (Klauber 1931). Occurrence of *Bd* in arid, desert environments is significant because desert anurans tend to be reliant on water bodies more so than species of more mesic environments resulting in higher local densities (Degenhardt et al. 1996) which may allow *Bd* to more virulently move through a population (Rowley and Alford 2007; Ryan et al. 2008). Although the prevailing environmental conditions at the sampling locations seem unsuitable to survival of *Bd*, microhabitat use (water bodies, retreat sites) and behaviors used by *L. berlandieri* (thermoregulation) could counteract the prevailing conditions by keeping the frog and thus the *Bd* at temperatures and humidities more conducive to both, because these frogs are obviously not exposing themselves to the extremes of the environment. *Lithobates berlandieri* is known to tolerate high salinities (McCoid 2005), similar to those conditions along the Salton Sea where the specimens were documented and collected. Interestingly, in laboratory culture *Bd* has been shown to survive, but grow poorly, at a pH of less than 6 (Piotrowski et al. 2004). The historically desert environs of the Coachella Valley have undergone urban and rural development to such an extent that extremely widespread agriculture, golf courses, and residential and private artificial landscaping have resulted in an elevated humidity and the expansion of mesic spatial and temporal conditions. Humidity is also greater along the shores of California's largest inland body of water, the Salton Sea, where the specimens were found. *Bd* is thought to be intolerant of extremely warm, dry conditions, and the occurrence of *Bd* in this type of environment is novel (Piotrowski et al. 2004).

Acknowledgments.—Taqman PCR testing for *Bd* in the Department of Conservation and Research for Endangered Species at the Zoological Society of San Diego was supported by a grant from the Annenberg Foundation. We thank Edward L. Ervin for reviewing a prior version of the manuscript.

Batrachochytrium dendrobatidis (*Bd*) is a chytrid fungal pathogen of amphibians that has been implicated in numerous amphibian extinctions and declines (Berger et al. 1998; Lips et al. 2006). The geographic distribution of this novel pathogen, however, is poorly known. While a number of reports are available from Africa (Goldberg et al. 2007; Smith et al. 2007; Weldon et al. 2004), Australia (Berger et al. 1998; Woodhams and Alford 2005), Europe (Bosch et al. 2007; Garner et al. 2005) and the Americas (Lips et al. 2006; Ouellet et al. 2005), we are aware of only two published reports from Asia. The first study (Garner et al. 2006) found no evidence of *Bd* in introduced populations of North American Bullfrogs (*Lithobates catesbeianus*, formerly *Rana*; Crother 2008; Frost et al. 2006) in Japan. The second study (Rowley et al. 2007) found no evidence of *Bd* in four native species or in frogs imported to Hong Kong, China. Herein, we provide preliminary data from surveys for *Bd* in Taiwan.

Methods.—On 3 October 2006, skin swabs were collected from 20 wild-caught adult frogs (representing 12 species in four families, taxonomy following Frost et al. 2006). Frogs were collected from ponds, streams, and roadside ditches in the vicinity of the Taiwan Forestry Research Institute's experimental forest at Lien Hua Chih Station (23.92°N, 120.87°E, Nantou County, elevation range of collection sites 600–700 m). Skin swabs were obtained by running a sterile cotton swab along the skin of the captured frog for approximately 30 seconds, focusing on the hands, feet, and pelvic region. A new pair of sterile gloves was used when capturing and handling each frog. Frogs were released immediately after the swabbing procedure. During collection, air temperatures ranged from 17–21°C. Skin swabs were preserved in 70% ethanol in 2.0 ml screw-capped microcentrifuge tubes and stored at room temperature. All samples were transported to the University of Michigan where they were tested for the presence of *Bd*.

The 20 swab samples and a total of 100 negative controls were randomized and tested for *Bd* using Taqman diagnostic quantitative PCR (q-PCR; Boyle et al. 2004). DNA was extracted from each sample and negative control following Hyatt et al. (2007) and q-PCR assays were performed in triplicate following Boyle et al. (2004). Samples containing PCR inhibitors were detected using VIC_{TM} Exogenous Internal Positive Controls (Applied Biosystems) and inhibition was overcome by dilution following Hyatt et al. (2007). Samples were considered positive if all three replicates indicated the presence of *Bd*. Samples testing positive in one or two replicates were re-assayed once.

Results.—One of the 100 negative controls tested positive for *Bd*, indicating a false positive rate for DNA extraction and *Bd* assay of 1%. All of the skin swab samples tested negative for *Bd* DNA in all three replicates except for one (from *Huia swinhoana*, Table 1). This sample initially tested positive for *Bd* in two out of three replicates. However, when this sample was re-extracted and three additional assays were performed, none of these replicates tested positive for *Bd* DNA. No dead or obviously diseased frogs were found at the study sites.

Discussion.—Taken together, the false positive rate of 1% for q-PCR and the lack of amplification in a second assay, it seems likely that the amplification of *Bd* DNA from the first assay of the *Huia swinhoana* sample was a result of cross-contamination (i.e., a false positive). While these data are from a relatively small sample in a small geographic area, they suggest that either *Bd* is absent from these sites in central Taiwan or that it occurs at such a low frequency that it was not detected.

Although we found no convincing evidence of *Bd*, it would be presumptuous to claim that it is absent from Taiwan. In fact, there have been unpublished reports of *Bd* from North American Bullfrog farms in southern Taiwan (L. Schloegel, pers. comm.). With relatively high levels of endemicity (27%; Yang 1998) and much of its land area at moderate to high elevations (where conditions for *Bd* would likely be optimal), Taiwan might be vulnerable to the kind of amphibian declines and extinctions that have been noted elsewhere. Additional surveys for *Bd* are urgently needed island-wide to assess the danger this pathogen may pose to Taiwan's amphibian fauna.

Acknowledgments.—We thank M.-F. Chiung, J.-L. Liu, and C.-S. Wu for help in the field collecting skin swabs. We also thank the Taiwan National Science Council for a travel grant for RML. The Institutional Animal Care and Use Committee at the College of Wooster approved the methods used in this project to collect skin swabs.

FORREST M. BREM*
The University of Memphis, Department of Biology
Memphis, Tennessee 38152, USA

**Corresponding author; e-mail: fbrem@memphis.edu*

There is evidence that amphibian chytridiomycosis, caused by the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*), is widespread throughout Mexico (Lips et al. 2004), New Zealand (Waldman et al. 2001), and South America (Ron and Merino 2000). Additionally, reports have documented *Bd* in parts of the USA (reviewed in Longcore et al. 2007), yet the full extent of its current geographical distribution in the United States remains unclear. *Bd* infections can cause mortality in metamorphosed amphibians, however pathogenicity varies among species (Davidson et al. 2003). More information about the distribution and effects of *Bd* will impact current management strategies and assist in the understanding of how *Bd* is spread. These data are especially important for amphibian populations which are not currently undergoing disease-related declines. Herein, we document *Bd* infections of two adult Southern Leopard Frogs (*Rana sphenocephala*) collected from Shelby County, Tennessee, USA.

During March 2008, multiple anurans (*Acris gryllus, Pseudacris triseriata, Scaphiopus holbrooki,* and *R. sphenocephala*) began breeding choruses following rain events in Tennessee. On 14 and 31 March 2008, we surveyed six ponds throughout Shelby County, Tennessee, in search of *R. sphenocephala* egg masses for a separate research project. On 14 March, we found two dead/moribund adult female *R. sphenocephala* within 2 m of each other along the east margin of one of the ponds (35.33861°N, 90.03944°W). The first specimen was heavily colonized by filamentous fungi and appeared to be dead for approximately 2–3 days. The second specimen was extremely moribund and was found with its ventral side facing up, with petechial hemorrhaging on the venter and feet. In addition to the hemorrhaged tissue, skin sloughs were present on the venter and all four appendages of the individual. On 31 March, we found a moribund adult male *R. sphenocephala* at a second locality (35.36278°N, 90.02194°W). This individual was also found ventral side facing up with hemorrhaged tissue. At each locality, we collected the moribund frogs from the water with forked sticks and placed each frog into a clean plastic container and into a cooler for transport to the laboratory at The University of Memphis. During transport to the laboratory, both frogs died (ca. 3 h after collection).

Batrachochytrium dendrobatidis can be diagnosed in fresh tissue by examining a piece of skin under a light microscope for *Bd* thalli (Longcore et al. 2007). Using latex gloves and sterile equipment, we collected a sample of sloughed skin from the venter of each frog and prepared a wet-mount slide of the freshly sloughed tissue and viewed it under 40×. After determining that the frogs were heavily infected with *Bd*, we fixed them in 10% formalin and preserved each entire specimen in 70% ethanol for additional photographs of the *Bd* infections. We then collected two additional, formalin-fixed, skin sloughs from the pelvic portion of each leg of the frogs. These sloughs were examined and photographed under 40×.

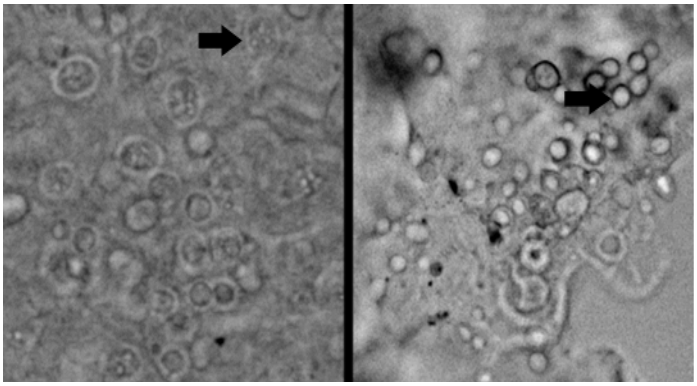

FIG. 1. Photographs, taken at 40×, of two skin sloughs from a female *Rana sphenocephala* with *Batrachochytrium dendrobatidis* thalli present, collected in Shelby County, Tennessee, USA. Left: arrow pointing to a thallus filled with zoospores; right: arrow pointing to a group of empty thalli.

Throughout each of the skin sloughs, we found heavy infections of *Bd* (Fig. 1). Additionally, on each skin sample, we found multiple life stages of *Bd*, ranging from empty thalli with discharge papillae to thalli filled with zoospores.

Transmission of *Bd* between individuals can occur by the spread of free-swimming zoospores (Pessier et al. 1999). Although data are lacking on how far zoospores can travel and infect a susceptible host, Johnson and Speare (2003) found that zoospores were viable after 3–6 weeks in water. Although it was not possible to determine the infection status of the other dead *R. sphenocephala*, we suspect that it was also infected with *Bd* because of the close proximity to the infected individual we collected. In addition, we did not perform necropsies on the *Bd* infected frogs and cannot say for certain that *Bd* infections were the cause of death of the two individuals. To our knowledge, this is the first published account of an infected metamorph anuran in Tennessee.

Acknowledgments.—K. Kramer provided the photomicroscope for images of the skin scrapes presented in this paper. T. Wilcoxen and an anonymous reviewer assisted with revising an earlier version of this manuscript. We complied with all applicable IACUC guidelines and obtained the appropriate scientific collection permits required to conduct this research.

Batrachochytrium dendrobatidis in *Ambystoma jeffersonianum* Larvae in Southern Indiana

ROBERT BRODMAN
Biology Department, Saint Joseph's College
Rensselaer, Indiana 47978, USA
e-mail: bobb@saintjoe.edu

and
JEFFREY T. BRIGGLER
Missouri Department of Conservation, 2901 West Truman Blvd
Jefferson City, Missouri 65102, USA

The amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) has been associated with amphibian declines and mass mortality (Berger et al. 1998; Bosch et al. 2001; Daszak et al. 2003; Lips et al. 2006). Infection is usually associated with the keratinized skin of post-metamorphic amphibians and keratin jaw sheaths of anuran tadpoles, however deaths have only been associated with post-metamorphic frogs (Berger et al. 1998; Daszak et al. 2003; Ouellet et al. 2005). Infections are sometimes associated with subtle skin lesions (Ouellet et al. 2005).

To our knowledge, *Bd* has not been associated with salamander mortality, salamander skin lesions, or detected in salamander larvae (Davidson et al. 2003; Pasmans et al. 2004; Speare and Berger 2000), although *Bd* was detected in several species of adult salamanders (Crummer et al. 2005; Davidson et al. 2003; Frias-Alvarez et al. 2008; Ouellet et al. 2005; Padgett-Flohr and Longcore 2005; Pasmans et al. 2004; Speare and Berger 2000). Most salamander larvae, such as ambystomatids, do not have keratinized jaw sheaths and only develop keratin in the skin late in development. Here we report our detection of *Bd* in pond-breeding salamander larvae with associated skin lesions.

On 28 May 2007, a random sample of 20 *Ambystoma jeffersonianum* (Jefferson Salamander) larvae was collected by dip-net from a pond in Morgan-Monroe State Forest in southern Indiana, USA (39.328°N, 86.423°W). The larvae were transferred to Saint Joseph's College in a single 8-L container filled with 4-L of pond water, for use in another study. The larvae were post-Harrison Stage 46 (Harrison 1969) with four toes developed on the front limbs and 3–5 toes developed on the hind limbs. The mean ± SD of TL was 43.3 mm ± 6.4 mm (range 33.1–56.7 mm). Examination of the larvae in the lab under 10× magnification revealed that 17 of 20 (85%) larvae had red skin lesions, usually on the hind limbs or the ventral surfaces of the jaw line, throat, body, or base of the tail; the two larvae with the largest lesions died during transit and were preserved in 70% isopropyl alcohol (Figs. 1a and 1b). The *A. jeffersonianum* larvae were kept in individual 500-ml containers with unchlorinated tap water that was changed twice weekly, at 13°C in an environmental chamber separated from other species in the lab. Larvae were maintained on brine shrimp nauplii and *Tubifex* worms following a protocol that has been successful in raising *Ambystoma* larvae (Brodman 1999, 2004; Brodman and Jaskula 2002). The three larvae without lesions survived through metamorphosis. The other 15 larvae with lesions or hemorrhages died 6–16 days after collection and were preserved in 70% isopropyl alcohol. In the most extreme cases two larvae lost parts of their feet and limbs (Fig. 1c and 1d).

PCR assay was used on five randomly selected larvae that had lesions and died to test for the presence of *Bd*. Two of the samples were whole larvae (smallest larvae) and a piece of the tail and one foot was removed from the remaining three (larger specimens). A portion of the tissue of each larva was transferred with clean forceps to 2.0 ml microfuge tubes, and tissue lysis buffer of 70% ethanol was added. Samples were shipped to Pisces

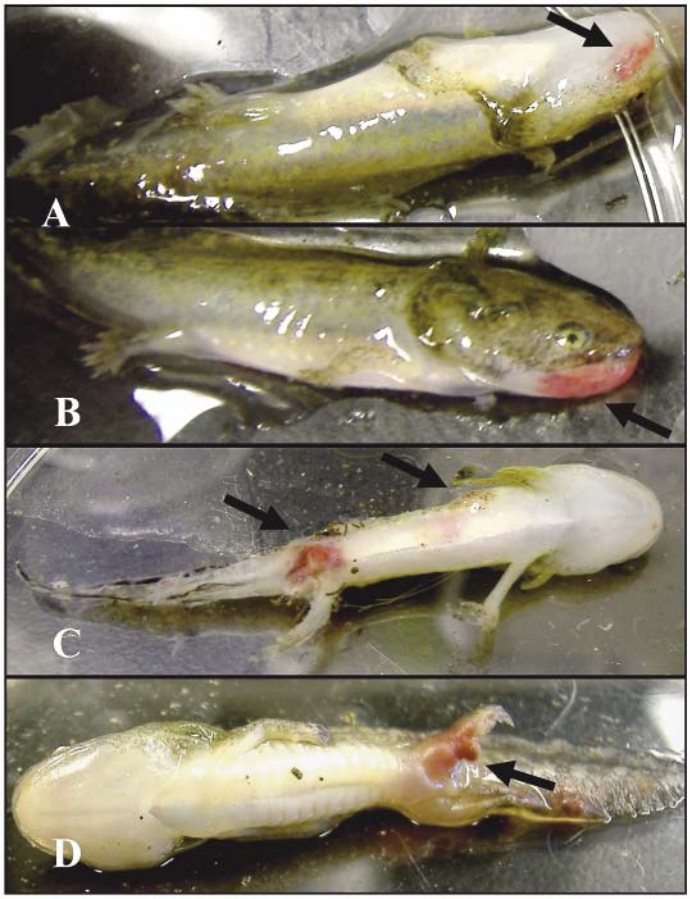

Fig. 1. *Batrachochytrium dendrobatidis* was detected in *Ambystoma jeffersonianum* larvae with skin lesions from southern Indiana, USA. Arrows indicate the following lesions: A and B show lesions on the upper and lower jaws, C shows foot and limb loss, and D shows lesion on hindlimb.

Molecular Laboratory (J. Wood, Boulder, Colorado, USA) for PCR (polymerase chain reaction) assay. Three of the five samples were *Bd* positive. The voucher specimens are deposited in the Saint Joseph's College zoology collection.

Annual larval surveys at the study site indicate that *A. jeffersonianum* and *A. opacum* (Marbled Salamander) populations have declined over the past ten years (R. Brodman, unpubl. data). Disease could be a cause of decline; however, we have not found dead or moribund larvae in previous years. To our knowledge, this is the first published case of *Bd* on larval salamanders. It should be noted that we have not determined the direct cause of mortality of these larval salamanders, nor the cause of the physical lesions, and it is possible that *Bd* and/or the associated physical lesions could be the cause of mortality.

Acknowledgments.—We thank J. Wood from Pisces Molecular, Boulder, Colorado, for analyzing tissue samples for *Bd*. We complied with all applicable institutional animal care guidelines and state permit regulations.

Amphibian declines and extinctions have been reported across the world and infection by a pathogenic chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), is one of the factors associated with this biodiversity loss (Berger et al. 1998; Stuart et al. 2004; Lips et al. 2006). *Bd* was first diagnosed in the West Indies in 2000, from histological studies of skin from declining populations of *Eleutherodactylus coqui* and *E. portoricensis* at El Yunque, Puerto Rico (Burrowes et al. 2004). Histological studies on seven different species of *Eleutherodactylus* collected between 1961 and 1978, revealed that 1976 was the earliest record of chytridiomycosis on the island, and this record corresponded to the last known individual of *E. karlschmidti* collected from El Yunque (Burrowes et al. 2004).

The purpose of this paper is to provide a geographical and taxonomic overview of the current distribution of *Bd* in Puerto Rico. This type of information, with corresponding sampling dates, represents a baseline for further research on the pathogen's origin, potential points of introduction, movement trends, and ecological requirements. In addition, it allows us to identify amphibian species that may be at greater risk from infection or extinction, and to develop appropriate management strategies.

Methods.—Frogs sampled in the wild for *Bd* were captured in individual plastic bags worn as gloves and inverted to prevent cross contamination. All native Puerto Rican amphibians, with the exception of *Bufo lemur,* were sampled. Individuals were examined for physical condition and sampled for *Bd* by swabbing their ventrum, feet and toes as described by Kriger et al. (2006), or toe-clipped following a modification of Twitty (1966) that allowed us to take tissue from different limbs of the frog. A fresh pair of powder-free nitrile gloves was worn every time a different frog

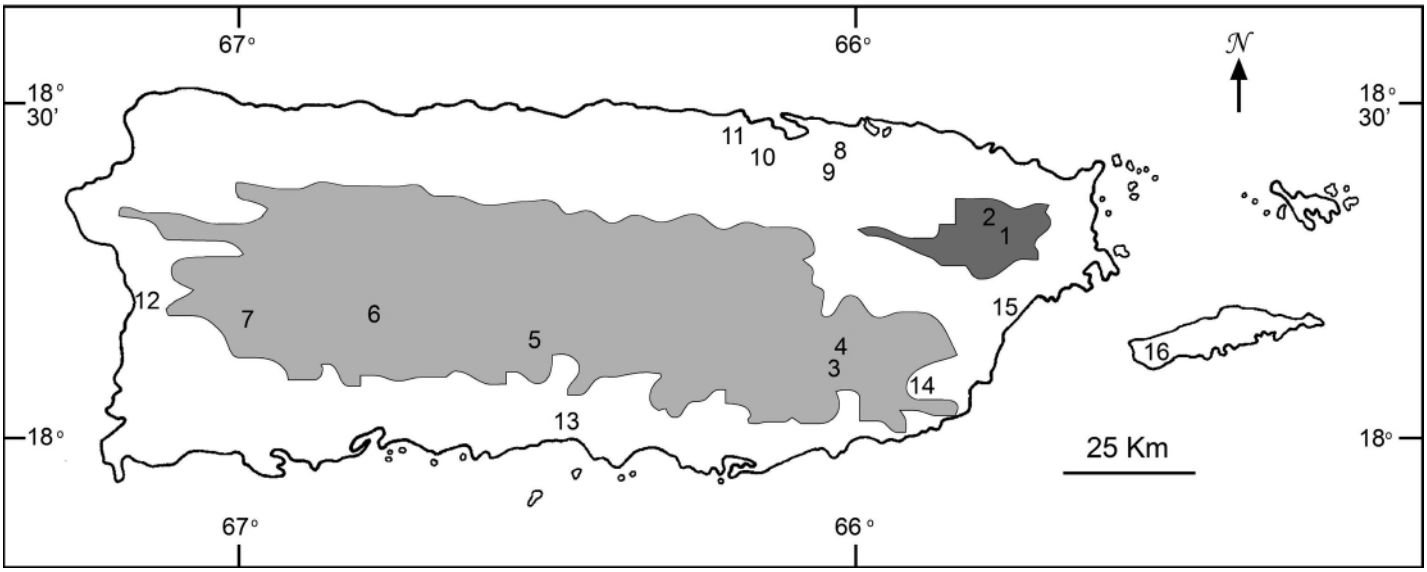

FIG. 1. Map of Puerto Rico showing locations of frogs sampled for *Batrachochytrium dendrobatidis* with the exception of Mona Island. Location numbers correspond to those described in Table 1. The light-shaded area represents the Central Cordillera and the dark-shaded area is The Sierra de Luquillo.

was manipulated. Survey sites were determined opportunistically according to other studies conducted by some of the authors. The number of frogs sampled per species and the timing in which species were sampled varied across this study (Table 1). Some species were sampled only once and *Bd* diagnosis is reported as positive or negative for that year only. Other species were sampled continuously during the dry and wet seasons in Puerto Rico, and for those, we use a dash next to the year to indicate ongoing *Bd* status until present (i.e., 2008; see Table 1).

Bd diagnostics was done by one of the following methods: histology of the skin performed by D.E. Green at the U.S.G.S. National Wildlife Health Center on wild-caught animal tissues collected in the year 2000, and on museum specimens from prior dates obtained from the University of Kansas Natural History Museum, University of Puerto Rico at Mayagüez, and the private collections of Richard Thomas and Rafael Joglar; Polymerase Chain Reaction (PCR) performed by Pisces Molecular (Boulder, Colorado, U.S.A.), following Annis et al. (2004); and Taqman quantitative PCR according to Boyle et al. (2004) at Zoological Society of London and University of Puerto Rico facilities. PCR methods were used for tissues from wild-caught animals from 2002 until present (Table 1).

Results.—A total of 2439 frogs were examined for *Bd* infection across Puerto Rico including two of its off-shore islands, Mona and Vieques. *Bd* was detected at seven of 17 locations sampled, in nine *Eleutherodactylus* species and one species of *Leptodactylus* (Table 1). *Bd* was not detected in another eight species of *Eleutherodactylus*, *Bufo marinus*, and *Rana catesbeiana*. For a few species that were examined from museum or private collections, geographic data was reported only as a region, or nature reserve. These species are reported within the closest locality sampled in our studies.

Discussion.—Previous studies suggested that *Batrachochytrium dendrobatidis* was introduced to Puerto Rico in the mid 1970s, in years characterized by cooler than average temperatures and a greater number of periods with more than five consecutive days without rain (Burrowes et al. 2004). Considering the advanced road infrastructure on the island, the disease could have spread easily and rapidly by humans to all environments that were suitable for its growth. As an epidemic pathogen during 1976–1981, *Bd* probably drove to extinction two species, *Eleutherodactylus karlschmidti* and *E. jasperi*, that were more dependent on water than any of the other 15 congenerics. *Eleutherodactylus karlschmidti* was a stream-dweller with fully webbed toes (Rivero et al. 1963), and *E. jasperi* was an obligate bromeliad dweller, considered more aquatic because it occurred within the inner axils, always flooded with water (Drewry 1986). At present the pathogen seems to be endemic above 600 m, occurring from the eastern Luquillo Mountains (El Yunque), throughout the Central Cordillera up to Maricao (Table 1 and Fig. 1). Species that are widespread in the island, such as *E. coqui*, *E. antillensis*, *E. brittoni* and *Leptodactylus albilabris*, are infected only at high elevations (Table 1). The absence of *Bd* from lower elevations in Puerto Rico may be explained by the high diurnal temperatures which are often above the thermal tolerance (17–25°C) reported for this fungus (Piotrowski et al. 2004). This suggests that high ambient temperatures may serve as a limiting factor for this disease in terrestrial, direct-developing anurans of the genus *Eleutherodactylus*, and point conservation efforts to the more vulnerable highland endemics in Puerto Rico. Nonetheless, in Costa Rica some lowland amphibians seem to cope well with low-level *Bd* infections (Pushendorf et al. 2006), and in Dominica, *Bd* has been associated with the drastic decline of *Leptodactylus fallax* at sea level (García et al. 2007). This suggests that *Bd* can infect amphibians at higher ambient temperatures, and that other factors such as behavior (Rowley and Alford 2007), reproductive mode, (Lips et al. 2003), or strain virulence (Berger et al. 2005) may influence vulnerability to chytridiomycosis among amphibian taxa.

It is evident that the range of responses of amphibians to infection by *Bd* varies among taxa, environmental conditions, climatic regimes and *Bd* strains (Berger et al. 2005; Retallick and

TABLE 1. Geographical distribution of *Batrachochytrium dendrobatidis* in Puerto Rico. Species names are followed by year of first diagnosis and sample size; a dash after a year indicates persistence until present. An asterisk denotes species for which exact localities were not available and, thus, have been reported within closest locality in their geographical range. The number in the first column corresponds to localities in the map (Fig. 1).

Miera 2007; Morgan et al. 2007). Puerto Rico is not an exception to these observations. Species extinctions, population extirpations from certain geographical areas, and population fluctuations in species that seem to resist the disease, have occurred on the island. Our data (Table 1) provides a valuable research tool to compare future changes in *Bd* spread, test for evolution of genetic strains, and study environment-specific variation in prevalence of this disease in amphibian communities.

Acknowledgments.—We are thankful to many students at the University of Puerto Rico, especially to C. A. Rodríguez, A. López, and P. Medina for their help in the field. Clyde Hutchinson and Michael Levy contributed to the training of one of the authors (AL) in PCR diagnostic techniques. Amphibian tissues were collected under Puerto Rican Department of Natural Resources permit numbers: DRNA 00-IC-21, 04-IC-003, 04-IC-062, 05-IC-051. Funding was provided by RANA (NSF DEB-0130273), Proyecto Coqui, and UPR-FIPI.

The pathogen responsible for the disease chytridiomycosis is the fungus *Batrachochytrium dendrobatidis* (*Bd*) (Berger et al. 1998), which has been detected in numerous localities around the world (Skerratt et al. 2007). In Italy, it has been detected in *Bombina pachypus*, *Rana latastei*, and *Rana catesbeiana* populations in the north (Stagni et al. 2004; Garner et al. 2006; T. Garner, pers. comm. 2008) and in a *Rana* kl. *esculenta/Rana lessonae* population in Umbria (Simoncelli et al. 2005; Di Rosa et al. 2007). *Bd* has also been detected on Sardinia (the second largest Italian island) in endemic populations of *Euproctus platycephalus* (Bovero et al. 2008). Here, we report surveys for the pathogen in 13 species of amphibian at 15 locations in Italy in 2007.

We hand captured individual amphibians and sampled them for *Bd* by rubbing a cotton-tipped swab over the body of each individual. Frogs were held separately prior to swabbing and technicians wore a new pair of gloves for each individual handled. As the frog was restrained, the swab was firmly rubbed back and forth 25 times over the drink patch and was also rubbed over the mouth and webbing between each toe. The swab was

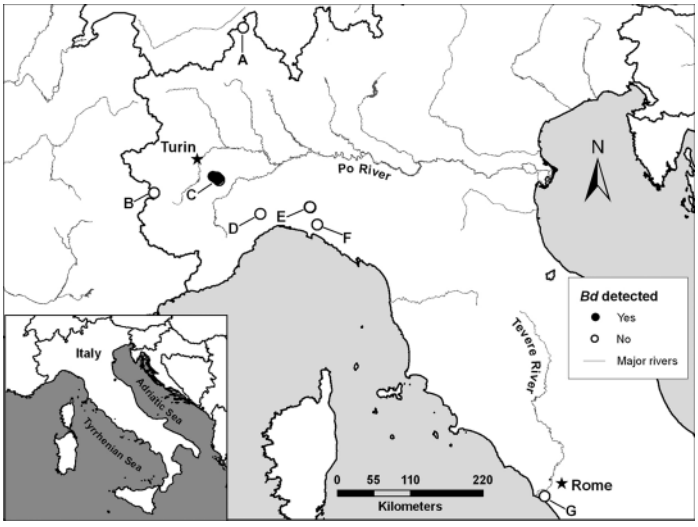

FIG. 1. Location of six study areas (A–G) in northern Italy where we sampled amphibians for the presence of *Batrachochytrium dendrobatidis* in 2007.

immediately inserted, cotton side down, into a 2-mL screw-cap tube containing 1 mL of 70% ethanol and stored upright. Vials were shipped to the laboratory for analysis, and each swab was analyzed individually for the presence of *Bd* DNA using PCR. The PCR assay was based on Annis et al. (2004), but modified to run for 45 cycles. Total DNA was extracted from swab samples using Qiagen DNeasy spin columns, amplified with *Bd*-specific primers targeting the ITS1 and ITS2 regions of the ribosomal DNA locus, and visualized with agarose gel electrophoresis. Samples were scored as negative or positive for *Bd* based on the absence or presence, respectively, of the expected 296 base pair amplicon. Known *Bd* DNA was used as a positive control in all PCR runs (J. Wood, Pisces Molecular, Boulder, CO, USA, pers. comm.). All field gear was cleaned with a brush and water and then sterilized using a dilute bleach solution between each sampling location.

We swabbed 45 amphibians and of these, 4 were positive for *Bd* (Table 1). We found *Bd* on all 3 *Rana catesbeiana* captured in a small farm pond near Turin (Fig. 1, Study Area C). *Rana catesbeiana* is a North America species introduced to Italy more than 50 years ago (Lanza 1962). It is less susceptible to chytridiomycosis-induced mortality than some other species of amphibian and may serve as a reservoir for *Bd* (Daszak et al. 2004; Garner et al. 2006). Out of 41 native amphibians tested, we only found one individual that was positive for *Bd.* The positive individual was 1 of 10 *R. esculenta* tested at 5 ponds in Study Area C. We did not find any frogs that were dead or that appeared to be sick. While only a small haphazard sample, this is the largest survey for *Bd* in Italy reported to date.

TABLE 1. Anurans that tested positive or negative for the presence of *Batrachochytrium dendrobatidis* in Italy in 2007. See Fig. 1 for the locations of the study areas A–G.

Historical Evidence for the Type Locality of *Sauromalus ater* Duméril, 1856

RICHARD R. MONTANUCCI
Department of Biological Sciences, Clemson University
Clemson, South Carolina 29634-0314, USA
e-mail: rrmnt@clemson.edu

The holotype of *Sauromalus ater* (MHNP 813) was collected during a circumnavigational voyage of the French corvette, *La Danaïde*, and presented, without locality, to the Muséum National d'Histoire Naturelle in Paris by Lieutenant M. Jaurès (Brygoo 1989). The lack of a type locality for *S. ater* has remained, ever since, a problem for taxonomists interested in *Sauromalus* (Hollingsworth 1998; Schmidt 1922; Shaw 1945).

Unable to study the holotype due to political conditions in Europe, Shaw (1945) believed he had uncovered clues in the literature as to its provenance. The details in a redescription of the type by Duméril and Bocourt (1870) as well as reference to traces of an interbrachial band mentioned by Mocquard (1899), suggested that the holotype might have originated from one of the islands off the southern gulf coast of the Baja California peninsula. However, Shaw (1945:284) did not restrict the type locality, but stated: "Not definitely known but undoubtedly one of the several islands in the southern part of the Gulf of California where this species is known to occur." Five years later, Smith and Taylor (1950) restricted the type locality to Isla Espíritu Santo without explicit justification (de Queiroz 1995). Perhaps Smith and Taylor (1950) selected this island because it is the largest one close to the port settlement of La Paz.

In Hollingsworth's (1998) systematic revision of the genus *Sauromalus*, he re-evaluated the meristic and color pattern characters of the holotype of *S. ater*, to determine its likely origin. Using a univariate statistical approach, Hollingsworth (1998) ruled out a number of populations as the potential source of the holotype because the holotype's character value fell outside the range limits of each sample. He concluded that the holotype was most similar to individuals from southern Sonora. Hollingsworth's (1998) also used multivariate approaches: a multivariate classification analysis placed the type specimen with the sample from southern Sonora, but using a discriminant function analysis, the holotype fell within the dispersion polygon for Isla San Francisco, adjacent to the boundary for Isla San Marcos, and farther away from the southern Sonora sample. Hollingsworth (1998) considered that the weight of the evidence supported the conclusion that southern Sonora was the likely origin of the holotype and he restricted the type locality to somewhere between Guaymas northward to the southern extent of the Llanuras de San Juan Bautista at Estero de Tastiota.

Montanucci (2000) reviewed Hollingsworth's (1998) methods for determining the type locality of *Sauromalus ater*, citing the problem of small sample sizes of the reference samples, the

intrinsic weakness of the univariate approach, and contradictions in the results of the multivariate analyses (see Montanucci 2000 for further discussion). Montanucci (2000) determined, using prediction intervals (Hahn and Meeker 1991), that most insular and southern coastal mainland sites dismissed by Hollingsworth (1998) could not be ruled out as the source of the holotype. He therefore argued that Hollingsworth (1998) had not conclusively demonstrated that southern Sonora was the type locality to the exclusion of the southern Baja California peninsula or adjacent gulf islands. Montanucci (2000) acknowledged that southern Sonora was a possible source for the holotype, but that without additional evidence, the question of the type locality remained unsettled.

Historical information has now come to light that provides convincing evidence as to the provenance of the holotype of *Sauromalus ater*. In 1945, noted historian Abraham P. Nasatir published a volume entitled *French Activities in California: an Archival Calendar-Guide.* According to Nasatir (1945), historians familiar with California history were well aware that in the mid-1800s the Pacific Region was an area of rivalry for power and influence by several nations including England, Russia, Spain, and the United States. What was not generally appreciated was the extent of the role played by France in this ongoing rivalry. In the preface of his book, Nasatir (1945) states that in 1924 he was awarded a traveling fellowship by the Sons of the Golden West to examine and catalog documents pertaining to the activities of France in California prior to statehood. He spent four months in 1924, and one month in 1925, working in the libraries and archives of Paris, and discovered an "immense amount of material" pertaining to California.

In the Ministry of Foreign Affairs, Nasatir studied the series "Correspondence Politique" containing letters between French officials and those of several other nations including États-Unis and Mexique. He also worked in the Archives du Service Hydrographique de la Marine, which contained reports of voyages, logbooks, and inventories. Relevant maps were stored in the Bibliotheque du Dépot des Cartes et Plans located in an adjacent building. Among the letters, manuscripts, reports, and maps listed by Nasatir (1945), I noted several that are relevant to the circumnavigational voyage (1839–42) of the French corvette *La Danaïde* under the command of Joseph de Rosamel. In early 1840, *La Danaïde* reached the west coast of México where it conducted nautical and hydrographic investigations, much to the dismay of Mexican officials. A letter dated 18 May 1840, from M. Baron Alleye de Cyprey, French Ambassador to México, to Maréchal Duc de Dalmatie, French Foreign Minister, states that His Majesty's corvette *La Danaïde* has raised the suspicions and fears of Mexican authorities by its work on that coast. De Cyprey further mentions that on the previous day, he received a note from M. de Cañedo, Mexican Minister of Foreign Relations, demanding an explanation for the activities of the corvette and expressing his astonishment that the ship is taking the liberty of charting the coasts of México without previously having obtained permission.

A 10.5-page manuscript entitled "á bord *La Danaïde*" listed in Nasatir (1945:313) includes a table of latitudes and longitudes, and observations and notes made at many places including the west coast of México, Lower California (Cabo San Lucas), Upper California (Monterey), as well as localities visited after the ship left the Pacific Coast area (e.g., Honolulu, Manila). Information about the ship's itinerary was found in the "Extrait du Journal de navigation de *La Danaïde* par de Rosamel." For Mexican localities where the ship anchored, it lists Acapulco, San Blas, Mazatlán, and Guaymas (Nasatir 1945:313). These records indicate that with the exception of Guaymas, Sonora, none of the localities known to be inhabited by *Sauromalus ater* was visited by *La Danaïde*.

The ship dropped anchor in the Bay of Guaymas during March of 1840, and two of the ship's men, Fisquet (sub-lieutenant of the vessel) and Garnault (a naval cadet), conducted a detailed survey to map the bay and its vicinity. Nasatir (1945:338) lists the Guaymas map under Portefeuille 171 bis, Division Number 6, as follows: No. 18 "Plan de la Rade de Guaymas et ses Environs, Levée en Mars, 1840 by M. Fisquet, Enseigne de Vaisseau." MS. Original "Voyage of *La Danaïde*" [Rosamel, rubric, — in Volume II of "Documents of *La Danaïde*."]. Rosamel et al. (2005:23) provide a general itinerary for *La Danaïde* and indicate the date of arrival at Guaymas as 14 March 1840. Although Nasatir (1945) lists only Fisquet for the preparation of the map of the Guaymas area, other sources (e.g., Orozco y Berra 1871; Uricoechea 1860) credit the naval cadet Garnault as well.

On the basis of official correspondence as well as the abbreviated contents of manuscripts and other documents (e.g., maps) listed by Nasatir (1945), it can be inferred that the French were very interested in charting the west coast of mainland México, probably for strategic reasons. However, the peninsula of Lower California was apparently of little or no concern to the French at that time. There is no record of *La Danaïde* having visited any of the islands in the Gulf of California or the port settlement of La Paz. The only peninsular locality listed is Cabo San Lucas (see below). The itinerary depicted by Rosamel et al. (2005:23) shows that *La Danaïde*, after reaching and then departing Guaymas, backtracked southward along the Sonoran coast to Mazatlán.

According to Shepard (1958), *La Danaïde* was stationed at Mazatlán from 19 April to 7 May 1840. While there and preparing to set sail for the Sandwich Islands (Hawaiian Islands), de Rosamel was informed by the crew of a schooner arriving from Santa Barbara that two Frenchmen had been killed and several others wounded during an incident (later known to historians as the "Graham Affair") at Monterey, the capital of Upper California. The governor of Upper California, Don Juan Bautista Alvarado, fearing a plot to seize control of the country, had ordered the general arrest of all foreigners, including 47 alleged conspirators (Americans and Englishmen among them), led by Isaac Graham from Tennessee. With news of this incident, de Rosamel decided to set sail immediately for Monterey to ascertain the veracity of this report, and if necessary, to avenge the deaths and protect any remaining compatriots. It can be inferred that while en route to Monterey, *La Danaïde* anchored at Cabo San Lucas, but spent little time there due to the urgency of the matter. Alternatively, the cape area could have been visited earlier while the vessel was charting the west coast of México, but this seems less likely as it would have diverted the ship away from its northward route along the coast.

According to Shepard (1985), de Rosamel arrived in the Bay of Monterey on 11 June 1840; the French corvette trained its cannons

on the capital and was prepared to reduce the small settlement to "a pile of adobe dust and splinters." But through discussions with local customs officials and a handful of French residents, de Rosamel quickly learned that the report of deaths and injuries to French citizens was erroneous. De Rosamel remained in Monterey for nearly a month to establish amicable relations with the residents and provision his vessel. On 8 July 1840, he drafted letters to Governor Alvarado and Baron de Cyprey recounting the circumstances of his visit to Monterey as well as related matters (Nasatir 1945:154–157). The following day (9 July 1840) de Rosamel set sail for Honolulu (Shepard 1985).

On the basis of the aforementioned information, it is clear that de Rosamel had an interest in charting the west coast of mainland México. The extended reconnaissance of the Bay of Guaymas and its vicinity by the officers and crew of *La Danaïde* provided the opportunity to collect *Sauromalus ater*. As indicated previously, no other localities occupied by this species are listed among the ports visited by the French vessel. It is my conclusion that the type specimen of *Sauromalus ater* was collected near Guaymas, and I therefore further restrict the type locality to the vicinity of Guaymas Bay, with the date of collection being sometime in mid-March 1840.

The classification analysis based on meristic data of the holotype of *Sauromalus ater* (Hollingsworth 1998) and the historical record presented here support the type locality restriction by Hollingsworth (1998) and its further restriction here. The specific epithet *ater* can now be assigned to the continental chuckwalla populations with confidence, thereby negating the need to designate a neotype with an arbitrary type locality. With regard to future research directions, it is not clear that all continental and insular populations are conspecific (see Petren and Case 2002). Molecular genetic studies should focus on the populations from the Baja California peninsula (Vizcaíno region southward), and the southern gulf islands to reassess their taxonomic status.

Acknowledgments.—I thank L. Sill and the interlibrary loan staff at Clemson University's Cooper Library, and M. Montanucci and C. Renfro of the Anderson County Library, Anderson, SC, for assistance in obtaining pertinent literature. I am also grateful to R. Espinoza and two anonymous reviewers who helped to improve the manuscript.

Catalogue of American Amphibians and Reptiles: The Beginnings

RICHARD G. ZWEIFEL*
Curator Emeritus, Division of Vertebrate Zoology (Herpetology)
American Museum of Natural History
New York, New York 10024, USA

**Present address:*
P.O. Box 16354, Portal, Arizona 85632, USA
e-mail: rzweifel@vtc.net

Early in 1960 several people came together in my office at the American Museum of Natural History and discussed what we thought of as an impending crisis. An amateur herpetologist had announced his intention to publish an updated version of Karl P. Schmidt's 1953 Check List of North American Amphibians and Reptiles, Sixth Edition. My feeling was that the proposal would be unlikely to yield a publication of high quality. Also, I had serious concerns about the form and content of any new checklist. The others present shared my concerns to a greater or lesser extent: Herndon G. Dowling (New York Zoological Society), William J. Riemer (University of Florida), and Philip W. Smith (Illinois Natural History Survey) were there, and possibly James Anderson (Rutgers University) and others whom I cannot now recall.

The Schmidt (1953) checklist had much the same format as the Fifth Edition (Stejneger and Barbour 1943), but with significant additions. Accounts of genera included synonymies more inclusive than in the earlier checklists, species and subspecies accounts (rather than species alone) each comprised of a brief synonymy with type localities incorporated, a generalized statement of range, and a "Common Name." Apart from some broad references cited in an opening section, bibliographic information was restricted to abbreviated citations in the synonymies.

The Schmidt checklist was a personal and idiosyncratic document. He stated (1953:2) "when [type localities] are vague, I have restricted them." He dropped the second *i* of *ii* endings in species names, or substituted *ei*. Most inconvenient for subsequent taxonomists, he introduced 29 new name combinations "[New comb.]," throughout the publication without explanation and without a means for the reader to find them other than by searching through the checklist. He dropped the convention of "enclosing the names of the authors of specific (trivial) names in parentheses when these names have been transferred from one generic combination to another" (1953:4). Apart from these technical matters, the range statements were often quite vague and occasionally erroneous, even given the state of knowledge when the manuscript was written.

It was apparent (at least to most of us) that a new single-authored checklist would suffer from many of the deficiencies of the Sixth Edition, even allowing for more input from other herpetologists than had that edition. Multiple authorship had potential advantages, but these might be more than offset by communication and editorial complications that could increase exponentially with the number of authors. Also of concern was the "engraved-in-stone" aspect of a hard-bound volume revised only every decade or so.

A possible solution that occurred to me was to publish a checklist incrementally in the form of individual accounts that could be assembled by the subscribers in a loose-leaf fashion. Among the many potential advantages were diversity of authorship, space to expand the sorts of information that had been restricted to a few lines of text in the earlier checklists, and room to add categories of information not previously covered. The loose-leaf format would have the additional virtue of permitting revisions of individual accounts without awaiting the production of an entirely new checklist. The suggestion was favorably received.

At the June 1960 annual meeting of the American Society of Ichthyologists and Herpetologists, I recommended to the Board of Governors that the Society consider replacing the hardbound, single-author checklist with a loose-leaf edition (Anon. 1960:393). President Norman Hartweg appointed a Committee "to investigate the desirability of issuing a new checklist of North American amphibians and reptiles." He instructed the Committee "to ascertain the support of the Society membership; to suggest the scope, content, and format of a new edition, if such is deemed desirable; and to determine the most economically feasible manner of producing a new checklist" (Anon. 1960:393). Subsequently, "Dr. Philip W. Smith presented a summary of comments from herpetologists on a proposed seventh edition of the check list of North American amphibians and reptiles. There were numerous opinions, but the consensus was that preparation should be made of a seventh edition or that a supplement, to be called a seventh edition, be made to the current sixth edition." "[Subsequent to the meetings, President Hartweg appointed the following persons to serve as a Committee on a North American herpetological checklist: Philip W. Smith, Chairman, Herndon G. Dowling, Alan E. Leviton, William J. Riemer, Hobart M. Smith, and Richard G. Zweifel]" (Conant 1960:398).

Hence, we began designing a format for the individual accounts, keeping in mind the need to expand upon both the categories in the Checklist's accounts and the variety of information provided. We decided that a typical species account should have the following eight sections: 1) Synonymy (incorporating type locality, catalog number of type specimen, deposition site, collector, and date of collection; 2) Content (names of subspecific taxa recognized); 3) Definition (descriptive statements characterizing the taxon); 4) Descriptions (citations to significant morphological descriptions); 5) Illustrations (citations to selected references with illustrations; 6) Distribution (a statement more detailed than the generalized ones in earlier checklists, always accompanied by a map with individual localities plotted); 7) Pertinent Literature (citations to sources of information not covered elsewhere in the account; 8) Etymology (derivation of the scientific name); and, of course, 9) Literature Cited. If subspecies were recognized, each would have a synonymy, definition, and (if needed) a Remarks paragraph. Wherever possible, accounts of anuran taxa would include an audiospectrogram. This format could be adapted as needed for accounts treating higher categories. A strict condition to be imposed on authors would be that no novel taxonomic conclusions could be advanced in an account. Where controversy existed, however, this should be recognized and documented.

We realized that such a publication would not be a checklist in the usual sense, but a catalog. The catalog would be made available by subscription in the hope that this would provide income to support the project. Initially a grant would be needed

as seed money. (The need for checklists of the less inclusive sort would eventually be filled by publications from the Society for the Study of Amphibians and Reptiles, The Herpetologists' League, and other organizations.)

At the April 1961 annual meeting of the ASIH a sample species account (marked "NOT PUBLISHED" to avoid future bibliographic complications) was distributed to the attendees for their comments, acting on President Hartweg's charge to the Committee in 1960. At this meeting, "The Committee of the Herpetological Check List, William Riemer, Chairman, received permission from the Board of Governors to proceed with plans for the check list, and was authorized to submit a proposal to the National Science Foundation for financing the check list on a three-year basis" (Anon. 1961:511). In addition to William J. Riemer being appointed Chairman, Wilfred T. Neill was added to the Committee.

Committee Chairman William Riemer was the person most responsible for getting the project moving. From his base at the University of Florida, he wrote the grant proposal to the National Science Foundation, and at the June 1962 ASIH meeting, "President Conant announced that the National Science Foundation had approved a two-year grant to the society, designated for the purposes of publication of the Herpetological Catalogue" (Peters 1962:868).

The first six Catalogue accounts were published in December 1963, followed by eight in September 1964, and eight in October 1965—all edited by Riemer. At the June 1966 ASIH annual meeting he reported that 8 accounts were in press, 12 at the printers, 34 being edited or reviewed, and 80 in preparation by authors. Clearly, the tasks involved in preparing manuscripts for the printer had become too varied and time-consuming to be done efficiently by one editor. In order to spread the work load, Richard Zweifel and James D. Anderson were appointed as Section Editors for Salientia and Caudata, respectively. The Section Editors would be responsible for editing manuscripts in their respective fields, leaving the Editor to see the accepted manuscripts through the press and distribution stages. These three edited 81 of the first 100 accounts. As the need developed in subsequent years, additional Section Editors were appointed and in later years editorial functions were further dispersed.

At the 1968 ASIH annual meeting Herndon Dowling, Chairman of the Herpetological Catalogue Committee, reported that the NSF grant supporting the Catalogue project was due to expire and that an extension of the grant period had been applied for. The extension was granted to 1970 but without additional funding. With about 600 subscribers by 1969 and 74 accounts published, the Catalogue was still not self-supporting. Although the ASIH Board of Governors was complimentary about the Catalogue project—"The Committee was highly commended for the work they have done on the Catalogue and were urged to continue this excellent project," (Highton 1970:799)—they declined to devote ASIH funds to its continuance.

Fortunately, the younger and more far-sighted board of the Society for the Study of Amphibians and Reptiles was willing to take a chance. "In 1970, the editors of the *Catalogue of American Amphibians and Reptiles* voted unanimously to request transfer to SSAR sponsorship from that of the American Society of Ichthyologists and Herpetologists which had supported the Catalogue since its beginning in 1963. That transfer was effected in 1971." (Moriarty and Bartholomew 2007:6).

William Riemer, who contributed so much to the establishment of the Catalogue, resigned his membership on the Catalogue Committee in 1969 and left the University of Florida for a position with the National Science Foundation in Washington. At that time Herndon Dowling became General Editor of the Catalogue and the editorial offices moved to the American Museum of Natural History, where his NSF-supported bibliographic project was quartered.[1] This project, however, was unable to become self-supporting and was terminated by the NSF in 1972 (Myers 2000:168). In 1974, I became General Editor of the Catalogue, while also keeping my position as Section Editor for Salientia. I continued as General Editor until 1981 and as Section Editor until 1986 when I resigned with retirement on the horizon.

The Catalogue has continued to grow and prosper. The inclusion of "American" in the name was not done lightly but implied an intention of including all the Americas, indeed the entire Western Hemisphere, in its scope; this intention has been realized. The penny-pinching days of trying to restrict as many accounts as possible to a single sheet have given way to more liberal funding, allowing multi-paged accounts, often with color illustrations. The Catalogue has become the "first stop" for anyone seeking information on the species and genera covered, with 840 accounts published by 2007. Itzchak Gilboa compiled a list (not published) of references cited in the first 400 accounts (through 1986), with no titles duplicated. I estimate that this list includes nearly 15,000 references.

Acknowledgments.—Kraig Adler, Charles W. Myers, and Itzchak Gilboa helped greatly in the preparation of this manuscript. Last but certainly not least, I thank my wife, Frances Zweifel, for her heroic efforts over 23 years (1963–1986) in producing all the more than 400 maps published from the very first account up to the time of our mutual retirement.

In an effort to improve the care and management of exotic animals there has been an increased interest in applying training in captive animal facilities. The training of captive animals has many advantages and has recently become more widespread. In one survey, 139 AZA accredited institutions reported performing at least some training with their animals (Good 2000). Additionally, most institutions that had formal training plans had formed them within the 15 years prior to the Good study.

Reinforcement training has been used successfully in captive animal facilities with such diverse groups as hoofstock (Phillips et al. 1998), marine mammals (Anderson et al. 2003), birds (Martin 2007) and even fish (Losey and Margule 1974). Despite the diversity of taxa in which these techniques have been found to be successful, the majority of published, objective training reports are focused on nonhuman primates (i.e. Laule et al. 2003; Prescott and Buchanan-Smith 2003; Schapiro et al. 2003). Conversely, reptiles, though capable of learning tasks, as shown in the basic learning literature (for a review see Burghardt 1977), are rarely the subject of published, applied learning accounts (for an exception see Weiss and Wilson 2003).

Training has been used to deal with various issues that arise with the management and display of captive exotic animals. Positive reinforcement training has been used successfully to increase animal activity (Myers 1977), facilitate breeding (Colahan and Breder 2003), decrease aggression (Bloomsmith et al. 1994), and even to elicit novel behaviors (Pryor et al. 1969). More commonly, animals have been trained to comply with basic husbandry and veterinary procedures (Basset et al. 2003; Laule et al. 2003). Some basic behaviors include "targeting" (the animal touches a target in response to a verbal cue), "shifting" from one place to another and "holding".

Training for these purposes has proven advantageous in several ways. For example, compliance training can decrease the stress of a procedure. In a study by Phillips et al. (1998) two groups of Bongo (*Tragelaphus eurycerus*) were subjected to a veterinary procedure. The group of Bongo that had been crate trained showed lower cortisol levels than the Bongos that were physically restrained for the procedure. Additionally, training can allow for other, more invasive, veterinary procedures to be performed without chemical or physical immobilization (Weiss and Wilson 2003). Positive reinforcement training may be particularly important in large and/or skittish animals (Pryor 1995). Training an animal to comply with a procedure in response to a cue rather than physically forcing it to comply prevents stress and possible injury for both keeper and animal.

The two main objectives for this project were to maintain a behavior that had previously been trained "target" and to train a new behavior of "hold" in a group of Aldabra Tortoises (*Geochelone gigantea*). "Target" is defined as having the animal touch a target stick, often a rod with a ball on the end of it, with their nose. "Hold" is defined as having the animal follow the target stick onto a platform and stand there without shifting their weight for 30 seconds. Targeting training officially started a year prior to this project for the purpose of facilitating moving the tortoises between sections of their exhibit. Problems occurred when staff attempted to weigh the tortoises. The "target" behavior, that had been used successfully to move tortoises between parts of the exhibit, failed in this new context. The target was used to try and guide the tortoises onto the weighing platform but this met with limited success. One animal refused to participate, one was spooked by the platform and had to be manually lifted onto it, and two would walk over the platform but not stop on it correctly. Only one tortoise successfully stepped on the platform and held long enough to get an accurate weight. Weighing these animals without their cooperation is particularly difficult because not only they are hard to move physically (as they often weigh hundreds of pounds), but trying to coerce them to move can be hazardous (animal care staff have been injured in the past). By specifically training a "hold" behavior, it was hoped accurate weights could be safely, quickly, and reliably obtained for all five tortoises.

Materials and Methods.—Subjects were two male and three female Aldabra Tortoises (*Geochelone gigantea*) housed at Zoo Atlanta. The two males each weigh ca. 136 kg and the three females ca. 91 kg each. Exact ages of the tortoises are unknown but they are all estimated to be over 50 yrs old. The tortoise exhibit consists of two outside yards and a heated indoor solarium.

Target sticks consisted of a dowel (1.07 m long, 6.4 mm diameter) attached to a blue-and-white pool float. The blue-and-white float was chosen as a target because it was too large to be swallowed by the tortoises. Additionally, blue and white are colors not typically associated with tortoise food items. Times were recorded with a stopwatch, and a thermometer was used to track the temperature during training sessions. The scale platform used for the weighing was a 1.2 × 1.2 m piece of wood which was 8.9 cm thick. Primary reinforcers used were mostly sticks of carrot and sweet potato, but also included melon and banana. Carrot and sweet potato sticks were used most often because they would not stick to debris, could be easily administered, and the tortoises responded well to orange-colored food. Orange was a salient color for these subjects. This was illustrated by the tortoises' repeated interest in orange colored items (e.g., colorful shoelaces) no matter how many times they encountered them and found them inedible. Although this species has not been tested for color vision, reports on related taxa show that color vision is likely (Liebman and Grada 1971; Ohtsuka 1985).

Design and Procedure.—Training sessions were held two or three times a week for three months. Sessions were ca. 45 min. in duration, and occurred at either 1400 or 1600 h. Training was

held indoors unless weather permitted the tortoises to be outside. Although the entire session was 45 min., each animal was worked with individually for only 5–10 min. Animals that were not being worked with individually had the behavior of "not interfering" reinforced. In this context, this consisted of placing food items that took longer for the animals to process (e.g., lettuces) at the edges of the exhibit. Thus, while the other tortoises were engaged with eating the freely available low preference items an individual could be worked with using the higher preference training food items.

Training was conducted by DB while observations and times were recorded by DEG. Training consisted of maintaining the "target" behavior and shaping the behavior of "hold." A clicker was used as a bridging stimulus during the training sessions; the clicker had been established as a secondary reinforcer prior to the initial target training. Training was initiated by placing the target in the subjects view and giving a verbal command in the form of "animal's name, command." Targeting was reinforced on a variable ratio schedule with an average ratio of two (VR2), meaning the behavior of targeting was reinforced after a random number, averaging two and with a range of one to three, of successful targets. Holding was reinforced for each successful hold of 30 seconds. The clicker was used when an animal successfully targeted or intermittently during the hold behavior.

Food items used for training were not part of the tortoises' general diet; they were only given in the context of training. The tortoises were fed daily, although in an attempt to keep motivational levels constant the tortoises were generally not fed until after the training session had ended. All food items not used during training were given out after the session was completed.

Scoring.—Hold times were measured from the moment when the subject first touched the target stick until it shifted its weight.

Results.—The criterion for successful training of the "hold" behavior was set at four consecutive successful holds of 30 seconds each. All five subjects achieved criterion within 25 trials with a mean of 15.8 (Fig. 1). At the end of the study, a mock weighing session was conducted. This procedure consisted of having the subjects step on the scale platform and hold there, without shifting their weight, for 30 seconds. The scale platform was novel to the tortoises when the weighing took place. Four of the subjects were successfully mock-weighed on a scale platform. The remaining subject, M2, was unavailable because of illness that caused him to cease eating and responding to the trainer. Before this project had taken place only one tortoise had been weighed successfully using a similar procedure.

Discussion.—This study demonstrates the practicality of training tortoises in compliance behaviors. All subjects were successfully trained to hold in a relatively short period of time (less than three months with only 10–30 min. a week of training per animal). The rapidity of the training was probably most attributable to the fact that the subjects had been target trained for the previous year.

These results may support the hypothesis that training of new behaviors can proceed more rapidly if the subject has had experience with training previously (Pryor 1999). Although these tortoises initially took months before even approaching the target, much less reacting to it appropriately (unpubl. data), shaping the target behavior into a 30-second hold was accomplished in a much shorter period of time. The concept of "learning to learn" is a well established one (Harlow 1949). However, to conclusively support this idea, a similar set of subjects who are naïve to training would need to be trained on the "hold" behavior. It is also important to note that other variables such as trainer experience, the animal's history and even temperature (especially for reptiles) can affect training results (Krekorian et al. 1968; Pryor 1999). However, institutions might consider training animals in the collection on at least one basic behavior, if not just for current purposes, but to possibly facilitate training of new behaviors in the future.

Additionally, it may be important to train flexibility into new behaviors. Problems with weighing these animals stemmed from the static way in which the target stick had been used in past training. Prior to this study, while target training, the keeper was always moving with the target stick (pers. obs.). Additionally, the target had only been presented at a height of about 7–8 cm off the ground. Thus, the tortoises had a reinforcement history only at one height and would not respond if target was held in any other position. Accordingly, the tortoises had acquired a fixed response of moving towards the target only when it was held at that height. They would not respond when the target was higher or lower and they would continue walking even if they had already encountered the target (they would push through the target instead of stopping). During this study, varying the height at which the target was presented and reinforcing the tortoises only for contacting the target, not walking through it, helped overcome these issues.

Reptiles can learn and this has implications in both applied and pure research areas. In the applied field, training can prove helpful in areas of animal husbandry (Laule et al. 2003). Animals can be trained to endure veterinary procedures without potentially harmful physical restraint or the risks associated with chemical immobilization. Additionally, they can be trained to shift from one part of the enclosure to another, facilitating cleaning of the exhibit as well as isolating the animal should a potentially threatening situation arise. Resistance to the idea of training reptiles may exist due to misconceptions of the time required to train a reptile to a useful task. However, training in turtles and lizards, given daily sessions, can be accomplished in only a matter of weeks (Ishida and Papini 1997; pers. obs.). The current results further support the hypothesis of the feasibility of training reptiles.

In addition to teaching captive animals useful behaviors, the application of positive reinforcement training techniques may provide other, broader benefits for these animals (Laule 1992). Training can also be considered a form of environmental enrichment (Laule 2003). Environmental enrichment can be defined as attempting to increase the mental and physical well-being of a captive animal. Training accomplishes this aim by allowing the animal to have a choice in their daily routine. At the very least, the animal can choose whether or not to participate in the training. Having such a choice may be good for captive animals, improving physical, and potentially psychological, health (Coe 1995; Mineka et al. 1986). Therefore, training animals presents an opportunity to increase an animal's well-being while making physical examination of its condition by staff much easier.

Training may have several other benefits. Positive reinforcement training may improve keeper-animal relationships and allow the animals to experience extra stimulation beyond that provided in

an otherwise highly static environment. Additionally, they have the opportunity to work for food, which may have benefits for animals as well by increasing a captive animal's opportunities for choice and stimulation through interaction (Laule and Desmond 1998). Training may also function as an indicator of general health, or expose health issues which may not otherwise be obvious. Markowitz et al. (1978) describe one such example where a Serval (an African cat), which had been trained to leap to obtain food, suddenly stopped responding. Upon physical examination, it was found that the Serval had developed a hernia, which in other circumstances might have gone undiagnosed. In the current study, subject M2 stopped responding to training sessions prior to the mock weighing. Later, the subject was diagnosed with a bleeding gastric ulcer.

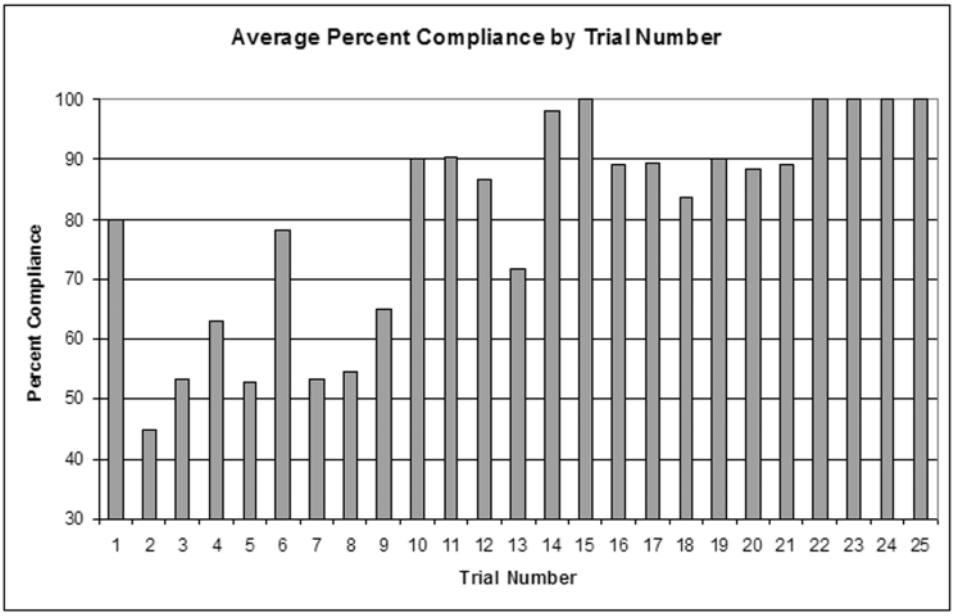

FIG. 1. Percent compliance with "hold" command averaged across five tortoises by trial number.

Another possible benefit of training concerns interactions between zoo staff and zoo visitors. Anderson et al. (2003) found that public animal training had several benefits. Visitors, after experiencing the public training, stayed at the exhibit longer and expressed more positive views on their zoo experiences when compared to visitors who only passively viewed the exhibit. In the current study, training sessions were often held during keeper talks where zoo visitors are encouraged to ask the keeper questions about the tortoises. This gave the keeper a chance to educate the public about positive reinforcement techniques, and their application in the zoo, while demonstrating those concepts first hand.

Having animals trained in basic husbandry behaviors can also be beneficial for research. For example, animals can be trained to voluntarily comply with blood draws, which can facilitate tracking hormones such as cortisol in blood levels (Phillips et al. 1998). Additionally, researchers can shape previously learned behaviors to facilitate behavioral testing. Kelling et al. (2006) shaped a previously trained "present paw" behavior into a "push" behavior that allowed for the behavioral testing of color vision in Giant Pandas (*Ailuropoda melanoleuca*). While many of these possible benefits described above are untested, if even some are actually beneficial, training should be considered as a valuable tool in captive animal management.

Although many examples of training have been published, rarely are they reported in a way that would allow for useful comparison. Several recent publications have noted this deficiency (Schapiro et al. 2003; Young 2002). These studies called for quantitative reports on both training and the effect of training, including details about the individual animals as well as the trainers and the training sessions. Although knowing that it is possible to train a particular species to perform a certain behavior is useful knowledge, details about the time required to implement a specific training protocol are essential to allow animal staff to determine the feasibility and utility of such a course of action. This report has included this information in an attempt to facilitate future comparisons. Additionally this report can serve as a guide to other facilities in how they might begin implementing training programs for their reptiles.

Acknowledgments.—We thank the staff of the Reptile Department at Zoo Atlanta for help with this project. We also thank Angela Kelling and two anonymous reviewers for their comments on this paper. This project was in compliance with the animal care guidelines in place at Zoo Atlanta.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 39, Number 1 (March 2008).

CAUDATA — SALAMANDERS

EURYCEA LONGICAUDA MELANOPLEURA (Dark-sided Salamander). **COLOR ABERRATION**. On 8 Sept 1999 during a rainstorm, a single female *Eurycea longicauda melanopleura* displaying an unusual color pattern was collected along with two normally patterned male individuals, 10 normal *Plethodon albagula* and two normal *Hyla cinerea* as they crossed the access road to the Mammoth Spring State Fish Hatchery 5 km S of Mammoth Spring, Fulton Co., Arkansas. The percent of aberrant pattern was determined by cutting the animal out of the photograph (Fig. 1) then cutting the patterned and unpatterned portions apart. The clippings were weighed separately on an analytical balance and the percent distributions determined. The same procedure was performed with a normally patterned individual for comparison. The colors present were the usual black speckling with yellow background. The normally patterned individual was unpatterned on 11.9% of its body, being patterned on 88.5% of its body (total = 100.4%, there was a 0.4% error in weighing). The aberrant individual was 45.9% unpatterned and 54% patterned (total = 99.9%, there was a 0.1% error in weighing). The aberrant salamander had 35.4% less patterning than the normal individual. This cause of this color aberration is unknown. Observations such as this further solidify the importance of using an array of diagnostic characteristics in addition to color and patterning whenever possible to identify species and/or subspecies. The specimen was deposited in the Arkansas State University Museum of Zoology herpetological collection (ASUMZ 23406).

WHEELER,** Biological Sciences, University of Arkansas Community College at Batesville, Batesville, Arkansas, USA (e-mail: bwheeler@uaccb.edu); and **STANLEY E. TRAUTH,** Department of Biological Sciences. P.O. Box 599. Arkansas State University, State University, Arkansas 72467, USA (e-mail: strauth@astate.edu).

PLETHODON DORSALIS (Northern Zigzag Salamander). **REPRODUCTION**. Few accounts of the nesting activity of *P. dorsalis* exist and are limited to those of Mohr (1952. Natl. Speleol. Soc. Bull. 14:59–60) and Miller et al. (1998. Herpetol. Rev. 29:38–39). Mohr (1952, *op. cit.*) reported 12 nests during three visits over a nine-year period to Mammoth Onyx Cave in Kentucky. All nests were observed in small cavities associated with fluted cave formations 1.5 m above the cave floor. Miller et al. (1998, *op. cit.*) found seven nests in a cave within the Central Basin of Rutherford County, Tennessee. Unlike the report of Mohr (1952, *op. cit.*), these nests were found in a series of fissures in the clay floor and not within cavities in the cave wall proper. Nests in both reports were found during the summer from 29 June to 02 August. Here, we report a nest of the Northern Zigzag Salamander found in a cave located in the Western Highland Rim of Tennessee.

An aggregation of *P. dorsalis* was found on 22 July 2006 in association with a series of fissures and crevices in the limestone wall of Cave Branch Cave (Tennessee Cave Survey No. HI3) located in Hickman County, Tennessee. The aggregation consisted of at least 23 adults dispersed within the fissures and crevices and exposed on rock faces ca. 30.5 m from the cave entrance and past the twilight zone. A single female (89 mm SVL) was found in attendance of a lone egg within a cavity behind a loose rock in this area ca. 75 cm above the clay/mud floor (Fig. 1). The ca. 4–5 mm egg was attached via the outer envelope to the floor of the cavity and the developing embryo lacked pigmentation and a tail bud indicating that oviposition occurred recently. Seven smaller adults including two males were in the immediate vicinity of the nest. The female and egg were transported to the laboratory to monitor development; however, the egg succumbed to a fungal infection eight days later.

Our observation supports the claims that females move underground in late spring or early summer to nest (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Univ. 347 pp.; Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC. 587 pp.). Although clutch size is reportedly small in *P. dorsalis*, ranging from 2–5 eggs in Kentucky (Mohr 1952, *op. cit.*) and 4–7 eggs in Tennessee (Miller et al. 1998, *op. cit.*), the single egg clutch reported here is unusually small. Enlarged ova were not visible through the abdomen of the attending female suggesting that all ova had been laid at the time of observation. If the clutch initially contained additional eggs, these eggs either succumbed to predation or infection.

FIG. 1. A female (89 mm SVL) *Plethodon dorsalis* in attendance of a lone egg within a cavity behind a loose rock in the wall of Cave Branch Cave, Hickman Co., Tennessee, USA.

MILLER**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA (e-mail: bmiller@mtsu.edu).

PLETHODON NETTINGI (Cheat Mountain Salamander). **HABITAT USE AND OVIPOSITION**. *Plethodon nettingi* is a federally threatened species endemic to high-elevation forests in the Allegheny Mountains of eastern West Virginia (Green and Pauley 1987. Amphibians and Reptiles in West Virginia. Univ. Pittsburgh Press, Pittsburgh, Pennsylvania. 241 pp.). Existing roads and trails are believed to serve as barriers to salamander movements and may fragment existing populations (USFWS 1991. Cheat Mountain Salamander Recovery Plan. U.S. Fish and Wildlife Service, Newton Corner, Massachusetts. 35 pp.). Presumably the microclimatic, vegetation, and structural characteristics that occur in and adjacent to trails during creation and maintenance (e.g., reduced overhead canopy and ground cover, higher soil temperatures) create unsuitable conditions for *P. nettingi* and other woodland salamanders. Moreover, individuals moving across trails are subject to disturbance from foot and mountain bike traffic. Therefore, management guidelines in the species recovery plan (USFWS, *op. cit.*) include the "establishment of a buffer zone of at least 300 feet around known *P. nettingi* populations within which trees and other vegetation should not be removed," and/or "re-routing of trails or other barriers to go around rather than through known populations."

On 9 June 2006 we observed a single *P. nettingi* under a small rock in the middle of the Railroad Grade Trail within the Monongahela National Forest near Davis, Tucker County, West Virginia, USA (39.0656ºN, 79.5239ºW; NAD 83). Similarly, on 10 June 2006 we observed a single *P. nettingi* under a rock in the middle of the Pointy Knob Trail, also within the Monongahela National Forest near Davis, (39.0364ºN, 79.4894ºW; NAD83). On the same trail, ca. 30 m away, we observed another *P. nettingi* in the middle of the trail attending 7 eggs (mean diameter 4.3 mm) attached to the underside of a small rock. At all locations, trail width was ca. 1–2 m and consisted of abundant small surficial rocks along with leaf litter, small woody debris, and moss/lichen. Dominant overstory vegetation included American Beech (*Fagus grandifolia*), Eastern Hemlock (*Tsuga canadensis*), Yellow Birch (*Betula alleghaniensis*), and Red Maple (*Acer rubrum*). Rosebay Rhododendron (*Rhododendron maximum*) and Red Spruce (*Picea rubens*) were present in the understory. Canopy closure at all sites was >75%. Our observations are significant as they document not only the presence of three *P. nettingi* on recreational trails used for a variety of purposes (e.g., hiking, mountain biking, skiing), but also the use of surface rock on a recreational trail as an

oviposition site. Our observations suggest that recreational trails may not necessarily inhibit movements by *P. nettingi*, and in fact may serve as suitable habitat when abundant cover objects (e.g., small rocks) and shaded ground conditions exist. However, if use of trail habitats by *P. nettingi* is more widespread than previously believed, recreational activities on these trails may constitute take, which is prohibited under the Endangered Species Act. We urge the appropriate regulatory agencies, i.e., U.S. Fish and Wildlife Service and West Virginia Department of Natural Resources, to both review the current status of *P. nettingi* and work with the U.S. Forest Service to mitigate possible impacts from the use of recreational trails on this species.

Our work was conducted under West Virginia Department of Natural Resources permit 2006.219, and supported by the USDA Forest Service Monongahela National Forest [Participating Agreement 05-PA-11092100-011 (144-908934)], USDA Forest Service Northern Research Station, and the USDI Fish and Wildlife Service Canaan Valley National Wildlife Refuge.

TARICHA GRANULOSA (Roughskin Newt**). SYMPTOMS OF POISONING.** *Taricha granulosa*, a salamander endemic to the moist coastal regions of the Pacific states, is known to manufacture and store the neurotoxin tetrodotoxin as an anti-predator defense (Stebbins 2003. Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, New York, New York. 519 pp.). Tetrodotoxin ($C_{11}H_{17}N_3O_8$), which is toxic to humans, blocks sodium-ion channels in nerve cells, causing hypotension and respiratory arrest (Torda et al. 1973. Med. J. Australia 1973:599–602; Sims and Ostman 1986. Ann. Emerg. Med. 1986:1094–1098). Symptoms of tetrodotoxin poisoning in humans as a result of puffer fish (Tetraodontiformes) ingestion are well-known (Torda et al. 1973, *op. cit.*, Sims and Ostman et al.1986, *op. cit.*), but only two accounts of tetrodotoxin poisoning from ingestion of *T. granulosa* have been reported (Brodie et al. 1974. Copeia 1974:506–511; Bradley and Klika 1981. J. Amer. Med. Assoc. 246:247). Alcohol consumption might have complicated symptoms in both cases, so accounts of newt poisoning in which tetrodotoxin acts alone are needed. Hence, I here provide a first-hand account of newt-induced tetrodotoxin poisoning.

At 1600 h on 09 Aug 2006, an assistant (Brendan Currey) and I captured an adult male *T. granulosa* (76.5 mm SVL, 102.0 mm tail, 15.0 g) in a bedrock-bottomed pool along a western Oregon stream (44.22927°N, 122.38838°W, WGS 84; elev. 211 m). The newt exhibited typical aquatic morphology (smooth skin, well-developed tail fin, and dark sides) characteristic of breeding males of this species (Stebbins 2003, *op. cit.*). While Brendan took a gag picture of me pretending to lick the newt, the shutter click caused the newt to flinch; as a consequence, its body just barely brushed the tip of my tongue, and I immediately noticed a bitter taste. Subsequently, I experienced a tingling, then burning sensation on the tip of my tongue. For the next 2 min, I flushed my mouth and tongue with copious amounts of water, at which point the burning subsided. At this point, I continued to survey. Eight minutes later, I experienced a sensation of dizziness with such rapid onset that it felt as if someone had hit me in the head, causing me to stumble to the ground. The sensation was that of my surroundings spinning; I found it extremely difficult to coordinate my speech or form coherent thoughts. My eyelids drooped involuntarily, and my vision was blurry and unfocused (Brendan indicated that my pupils were fixed dilated). This state of dizziness, coupled with a general loss of feeling (numbness over most of my body) lasted for a full 20 min. Thirty minutes after the event, I had regained some feeling in my body, and had enough muscle control to walk and talk, though I was still unable to coordinate my thoughts. My eyelids still drooped, and my vision was still blurry. Interestingly, I had previously sustained a significant back injury and had been in considerable pain prior to the newt-licking event; as the dizziness passed, I noticed that my back was totally numb, and it remained so for almost an hour. Brendan also indicated that my eyelids continued to droop for ca. 90 min, and my vision remained blurry and unfocused (with dilated pupils) for ca. 2.5 h. Following cessation of these symptoms, I had a headache that lasted several hours.

The symptoms I experienced in this case, including dizziness, numbness, and dilated pupils, are similar to those previously reported (Bradley and Klika 1981, *op. cit.*), and thus appear representative of tetrodotoxin poisoning from *T. granulosa*. Besides illustrating its potentially serious consequences, this account provides clues to consider in cases where *Taricha* poisoning may be suspected.

I thank Brendan Currey for his assistance in making observations and Marc P. Hayes for suggestions.

TARICHA GRANULOSA (Rough-skinned Newt)**. REPRODUCTION.** *Taricha granulosa*, one of three salamandrids native to the Pacific Coast of North America, generally exhibits a biphasic life history, with aquatic larvae developing into terrestrial forms which return to the water to breed (Stebbins 2003. Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, New York. 519 pp.; Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. Univ. Press of Idaho, Moscow. 332 pp.). In lowland regions, such as the Willamette Valley of Oregon, the breeding period is reported as February through July (Chandler 1918. Oregon Ag. Coll. Exp. Bull. 152:1–24; Pimentel 1960. Am. Midl. Nat. 63:470–496). In this note, we increase the known reproductive interval with an observation of breeding by *T. granulosa* in November from western Oregon.

At 1430 h on 8 Nov 2006, we collected six adult *T. granulosa* in the water-filled concrete fish ladder at the Alsea Fish Hatchery, Benton Co. (44.422°N, 123.551°W; WGS 84; elev. 116 m), Oregon, USA. Based on the presence of secondary sexual characteristics (well-developed tail fin, smooth skin, swollen vent, and rough clasping patches on feet and limbs) in the males and a gravid condition (evidenced by a swollen abdomen, indicating the presence of well-developed eggs) in the females, five of these

were in breeding condition. Of these five newts, four were two amplectic pairs (Pair 1: male 104.8 mm SVL, female 63.5 mm SVL; Pair 2: male 88.9 mm SVL, female 66.7 mm SVL), and the fifth was an unpaired male (85.7 mm SVL). The portion of the ladder in which we observed the newts had no visible flow, was partially covered with duckweed (*Lemna* sp.), and ranged in depth from 45–60 cm. Water temperature was ca. 15°C. Both amplectic pairs were swimming slowly near the water's surface when caught; occasionally, they would investigate a floating log or swim towards the bottom of the pool. The male of Pair 2 was observed "chin-rubbing" the snout of the female with which he was paired prior to capture. The male of Pair 1 had an extremely swollen vent, from which a whitish secretion was issuing when captured. Though actual egg deposition was not observed, the female newts' abdomens were enlarged to a degree similar to that of others observed by CJR in the Willamette Valley which deposited eggs < 48 h after courtship (amplexus and fertilization).

Notably, 14 recently transformed *T. granulosa* were also captured in the pool. Mean size of 3 of these metamorphs was 27 mm SVL; most had stubby (1 mm) gill remnants. These animals were either resting on floating debris, attempting to climb the concrete sides of the outflow, or were swimming awkwardly, attempting to make contact with an object on which they could climb out of the water. The presence of these metamorphs is significant because it indicates successful breeding earlier in the year (neither larvae or adults can overwinter in the fish ladder due to the high flow present in this structure during winter months).

Taricha granulosa in montane situations (particularly in the case of neotenic forms) are known to breed in fall, depositing eggs as late as October (Marangio 1978. NW Sci. 52:343–350; Garber and Garber 1978. J. Herpetol. 12:59–64). However, this represents the first record of lower-elevation breeding in western Oregon between July and February, possibly following breeding earlier in the year. Further investigation is needed to determine the extent of this phenomenon and its significance to *T. granulosa* life history.

ANURA — FROGS

CHAUNUS JIMI (NCN). **ENDOPARASITES**. Parasites may exert negative impacts on their hosts, such as morphological modifications, decrease in growth and fecundity, disturbance on feeding habits, even causing death of hosts (Marcogliese 2004. Ecohealth 1:151–164). *Chaunus jimi* (Stevaux 2002. Rev. Bras. Zool. 19:235–242), occurs in northeastern Brazil (Frost 2007. Online Reference. Version 5.0 http://research.amnh.org/herpetology/amphibia/index.php). We examined 37 *C. jimi* from the Universidade Regional do Cariri: (LZ-URCA 469–500, 503, 504. 506–508) from five municipalities of Cariri region, Caririaçu (7.033°S, 39.283°W), Crato (7.233°S, 39.4°W), Mauriti (7.38°S, 38.766°W), Várzea Alegre (6.783°S, 39.283°W) in the state of Ceará, and Exú (7.5°S, 39.716°W) in the state of Pernambuco. Body size (SVL) was measured to the nearest 0.1 mm, and the respiratory tract removed and examined for parasites under a stereomicroscope. The parasites were mounted on glass slides, identified, and preserved in 70% ETOH. We found *Rhabdias fuelleborni* (Nematoda: Rhabdiasidae) in the lungs of these toads. The overall prevalence was 81.1% (30/37) and the mean intensity of infection was 18.7 ± 25.9 (range: 1–97). There was no relation between SVL and intensity of infection (spearman rank correlation, $r_s = 0.15$; $t = 0.80$; $p = 0.43$). Species of *Rhabdias* are common pulmonary parasites of bufonids (Vicente et al. 1990. Rev. Bras. Zool. 7[4]:549–626), however *C. jimi* represents a new host record for *R. fuelleborni*. Voucher specimens of the parasites were deposited as LZ-URCA 600–697.

LEPTODACTYLUS DIPTYX (Tropical Bullfrog). **ENDOPARASITES**. *Leptodactylus diptyx* occurs in the Lower Chaco and oriental region of Paraguay, the eastern lowlands of Santa Cruz (Bolivia), and northern Argentina (IUCN 2007. Conservation International and NatureServe. Global Amphibians Assessment. http://www.globalamphibians.org. Accessed 22 Oct 2007). To our knowledge, no previous reports of parasites exist for *L. diptyx*. Herein we report *Catadiscus* sp. (Trematoda) and *Centrorhynchus* sp. (Acanthocephala) in *L. diptyx* from Argentina. Two adult *Catadiscus* sp. were found in the large intestine and five acanthocephalan larvae *Centrorhynchus* sp. in the coelomic cavity of a female *L. diptyx* (27.6 mm SVL) from the herpetological collection of Universidad Nacional del Nordeste (UNNEC 9000) collected 22 Nov 2006, Corrientes (city), Corrientes Province (27.466°S, 58.783°W, datum: WGS 84; elev. 65 m). *Leptodactylus diptyx* is a new host record for *Catadiscus* sp. and *Centrorhynchus* sp.

We thank L. Lunaschi for verification of the identification of the organisms.

LEPTODACTYLUS PODICIPINUS (Pointedbelly Frog). **PREDATION.** Amphibians are common prey for a great variety of vertebrates, arthropods, and even carnivorous plants (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York; Pough et al. 1998. Herpetology. Prentice-Hall, New Jersey). The fishes known locally as "lambaris" or "tambiús" live strictly in fresh water, and have the greatest number of species

FIG. 1. Adult female *Leptodactylus podicipinus* wounded, showing exposed intestines and eggs in a stream at the Parque Ecológico do Baguaçú, Araçatuba municipality, state of São Paulo, Brazil.

in the family Characidae. *Astyanax* is the most common genus in the state of São Paulo (Nomura 1975. Rev. Brasil. Biol., Rio de Janeiro, 35[4]:775–798). Many characids are nocturnal, have good visual acuity (Orsi 2001. Dissertação mestrado. Instituto de Biociências, Universidade Estadual Paulista, Botucatu), and forage in an opportunistic fashion (Bennemann et al. 2000. Peixes do Rio Tibagi: Uma Abordagem Ecológica. Londrina, Ed. Universidade Estadual de Maringá. 62 pp.). Here we report the predation of an adult female *Leptodactylus podicipinus* by a shoal of "lambaris" (*Astyanax altiparanae*).

On 3 Oct 2007 at 1600 h, in a stream at the Parque Ecológico do Baguaçú, Araçatuba municipality, state of São Paulo, Brazil, an adult female *Leptodactylus podicipinus* was observed wounded, showing exposed intestines and eggs (Fig. 1). When the frog was disturbed by our presence, it jumped into the water. At the same instant, a shoal of *A. altiparanae* attacked and consumed the wounded frog.

LITHOBATES CATESBEIANUS (American Bullfrog) **PREY.** *Lithobates catesbeianus* is one of the most harmful invasive species in the world, being introduced in the Caribbean Basin, South America, Europe, and Asia (Lowe et al. 2000. 100 of the World's Worst Invasive Alien Species. The Invasive Species Specialist Group, 12 pp.; IUCN, CI, and NatureServe 2006. Global Amphibian Assessment. <www.globalamphibians.org>, accessed on 09 April 2008). This species was introduced in Brazil in the 1930s for commercial breeding, where, due to poor management practices and high survival of individuals in wild habitats, feral populations became established in many regions, especially in the Atlantic Rainforest (Giovanelli et al. 2007. Biol. Invasions 9:1–6).

FIG. 1. Dissected stomach of Bullfrog (*Lithobates catesbeianus)* containing a juvenile *Bothrops jararaca*.

There are few records of predation on snakes by *L. catesbeianus* and these mostly involve species that occur within the frog's native range (but see: Silva et al. 2007. Herpetol. Rev. 38:443). On 12 Jan. 2008, during fieldwork in Ponte Nova municipality, Minas Gerais state, southeastern Brazil (20.3710667°S, 42.9250028°W; datum WGS 84; 412 m elev.), CBCF collected a *L. catesbeianus* (female, SVL 15.93 mm, 429.9 g), which contained in its stomach a juvenile *Bothrops jararaca* (305 mm SVL, 5.9 g), and a partially digested treefrog (Fig. 1), probably an adult *Hypsiboas crepitans*.

The juvenile *B. jararaca* (MZUFV 1514) was deposited in the herpetological collection of Museu de Zoologia "João Moojen," Universidade Federal de Viçosa, in Viçosa, Minas Gerais. We thank Universidade Federal de Viçosa for transport logistics, Jorge Dergam for English translation assistance, and Robert Hansen for suggestions on the manuscript.

DA SILVA** (e-mail: etsbio@yahoo.com.br), **OSWALDO P. RIBEIRO FILHO** (e-mail: oribeiro@ufv.br), and **RENATO N. FEIO** (e-mail: rfeio@ufv.br), Departamento de Biologia Animal, Universidade Federal de Viçosa, 36571-000 Viçosa, Minas Gerais State, Brazil.

OSTEOCEPHALUS OOPHAGUS (NCN). **TERRESTRIAL BEHAVIOR.** *Osteocephalus oophagus* is one of seven *Osteocephalus* species known to occur in the Brazilian Amazon, and one of three found at the Biological Dynamics of Forest Fragments Project (BDFFP) in the state of Amazonas (Zimmerman and Simberloff 1996. J. Biogeog. 23:27–46). *Osteocephalus oophagus* is a phytotelm breeder with oophagous tadpoles; adults spend most of their time in the canopy. The breeding season for

O. oophagus, as with other *Osteocephalus*, generally coincides with the rainy season (Jungfer and Weygoldt 1999. Amphibia-Reptilia 20:235–249). Individuals of this species have only previously been observed near the ground when reproducing in terrestrial bromeliads (Jungfer and Weygoldt 1999, *op. cit.*). Here I report terrestrial behavior previously undescribed for *O. oophagus*, but that has been observed in two other *Osteocephalus* species in the Ecuadorian Amazon (Deichmann and Williamson 2007. Herpetol. Rev. 38:189).

While searching 5 × 5 m quadrats for leaf litter herpetofauna in continuous forest during the wet season at Fazenda Dimona (BDFFP), we found 2 *O. oophagus* females hidden in the leaf litter. The first individual (56.8 mm SVL, 8.51 g) was found on 9 May 2007 on the ground in terra firme forest at ca. 1030 h, buried well under the litter layer. The second female (56.7 mm SVL, 9.81 g) was found the same day at 1400 h in a position similar to the first. When encountered, both were seemingly asleep. Upon handling, they became aroused and attempted to escape. Both frogs were photographed and released on site later the same day.

The leaf litter habitat has largely been ignored in studies of *Osteocephalus* because of the traditional view that the genus is strictly arboreal. However, the observations presented here, as well as accounts of this same behavior in *O. planiceps* and *O. yasuni* (Deichmann and Williamson 2007, *op. cit.*), suggest that the leaf litter might be an integral habitat for females during the breeding season and should be searched by investigators. Further research is needed to determine why females of these generally arboreal species spend time on the ground, whether other species of *Osteocephalus* show similar behavior, and whether individuals utilize leaf litter habitat in the dry season as well as the wet season.

I thank the staff of the BDFFP for logistical support and João de Deus Fragata Farias for field assistance. This observation was made during dissertation research supported by grants from the Conservation, Food, and Health Foundation, Louisiana Governor's Office of Environmental Education and Biograds. Work in Brazil was conducted with permits from CNPq (EXC 006-06-C) and IBAMA (n 222/2006).

OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). **DIET**. *Osteopilus septentrionalis* is a large, invasive hylid in Florida, where it has become common throughout the central and southern portions of the peninsula. In Florida, *O. septentrionalis* is known to feed on squamates, including three species of introduced lizards (Meshaka 2001. The Cuban Treefrog in Florida. Univ. Press of Florida, Gainesville. 192 pp.) and the native Florida Brownsnake, *Storeria victa* (Maskell et al. 2003. Herpetol. Rev. 34:137). Here we report the predation of a native lizard by *O. septentrionalis*.

At 1542 h on 4 Jan 2007, while checking PVC pipe refugia for a study at Wekiwa Springs State Park, Apopka, Florida, USA, we discovered a 40 mm SVL *O. septentrionalis* depredating a 39 mm SVL adult male *Anolis carolinensis* (Green Anole). The frog was facing downwards within the pipe using its forearms to force the lizard head-first into its mouth, while using its half-extended rear legs to support itself on the inside surface of the pipe. We removed the pipe from the ground to photograph the predation event from the end of the pipe to which the frog and lizard were closest. We used a "plunger" to chase the frog from the pipe, and upon capture it dropped the lizard, which appeared stressed but relatively unharmed. We released the Green Anole into palmetto adjacent to the pipe.

PHYSALAEMUS CUVIERI (Dwarf Frog). **ENDOPARASITES.** Vicente et al. (1991. Rev. Brasil. Zool. 7:549–626), in an inventory of the nematode parasites of amphibians in Brazil, reported the occurrence of *Cosmocerca* sp. in the digestive tracts of Hylidae, Bufonidae, and Leptodactylidae. Between Sept 2002 and Feb 2003, 286 individual *Physalaemus cuvieri* (mean SVL = 284 ± 3.04 mm; range 157–354 mm) were collected in two areas of Brasília and were deposited in the Coleção da FTB (Brasília, DF). The body cavity was opened and the stomach, small, and large intestine were removed and examined; 17 adult nematodes were found (prevalence: 4.2% and mean intensity: 1.42). Only female *Cosmocerca* were found, thus making species determination very difficult. This note reports the first occurrence of *Cosmocerca* sp. in *Physalaemus cuvieri* in Brazil. Nematodes were deposited in the Coleção Helmintológica do Instituto de Biociências de Botucatu, Botucatu, São Paulo, Brazil (CHIBB 1428).

We thank Reinaldo J. Silva (Universidade Estadual de Botucatu, Brazil) for identification of the nematodes, and Leonardo Inglês for help with fieldwork.

RANA CATESBEIANA (American Bullfrog). **TADPOLE GIGANTISM and DEFORMITY**. On 11 Dec 2007, individuals from Arizona State University (ASU) and Arizona Game and Fish Department (AZGF) harvested roundtail chub *Gila robusta* from a stock pond at Bubbling Ponds State Fish Hatchery (BPFH) in Cornville, Yavapai Co., Arizona, USA. The pond (0.7 ha, 1.4 million gal.) was completely drained and seined for fish removal. *Rana catesbeiana* tadpoles also occupied the pond and were abundant (most were 40– 80 mm TL). One extraordinary specimen was discovered measuring 195 mm TL (197 mm prior to preservation in alcohol) (Fig. 1A) and was preserved for deposition into ASU Natural History Collections (ASU 35975). Bolek and Janovy (2004. Herpetol. Rev. 35:376–377) reported a 190 mm specimen as the largest of its kind.

The ponds at BPFH are fed from an artesian spring and pond temperature annually ranges from 11–22°C. Pond was stocked with 750 adult *G. robusta* on 26 Jul 2006. At harvest, the pond contained Chara (*Chara* sp.) and Eurasian Water-milfoil (*Myriophyllum spicatum*). Fish were fed pelleted catfish diet enriched with spirulina and krill (Rangen®) dispensed at a rate of 2.25 kg twice daily. Additionally, fish were curatively treated for illness once with potassium permanganate and twice with a copper sulfate / citric acid solution (independent treatments, each at 0.75 ppm).

The tadpole appears to have stalled at Gosner Stage 25, as no hind-limb buds are externally evident (Gosner 1960. Herpetologica 16[3]:183–190; Fig. 1B). Subsequently, the specimen was x-rayed to investigate any skeletal basis for deformities. Inspection of the lateral x-ray indicated possible hind-limb development (Fig. 2A), but inadequate resolution made it difficult to determine whether markings were real or an artifact of the superimposition of intestinal tissues. Additionally, the specimen is lacking a right eye and x-ray imaging shows that the tadpole's skull, though not completely calcified, appears asymmetrical in density (Fig. 2B).

Other investigators have shown that metamorphic deformities and gigantism in tadpoles are thyroid-related (Rocek et al. 2006. Paleobio. 32[4]:666–675; Rot-Nikcevic and Wassersug 2003. Dev. Growth Different. 45[4]:321–325). Thyroid hormone levels are subject to disruption by parasites, UV radiation, and chemical or metal contamination, among other stressors (Bridges et al. 2004. Env. Sci. Pollution Res. 11[4]:233–239; McDaniel et al. 2004. Water Qual. Res. J. Canada 39[3]:160–174). Specifically, copper contamination in both aqueous and solid forms has been implicated as contributing to deformities in amphibians (McDaniel et al. 2004, *op. cit.*). Given that that the pond was treated with copper sulfate, it likely represents a chemically unnatural environment for tadpole development.

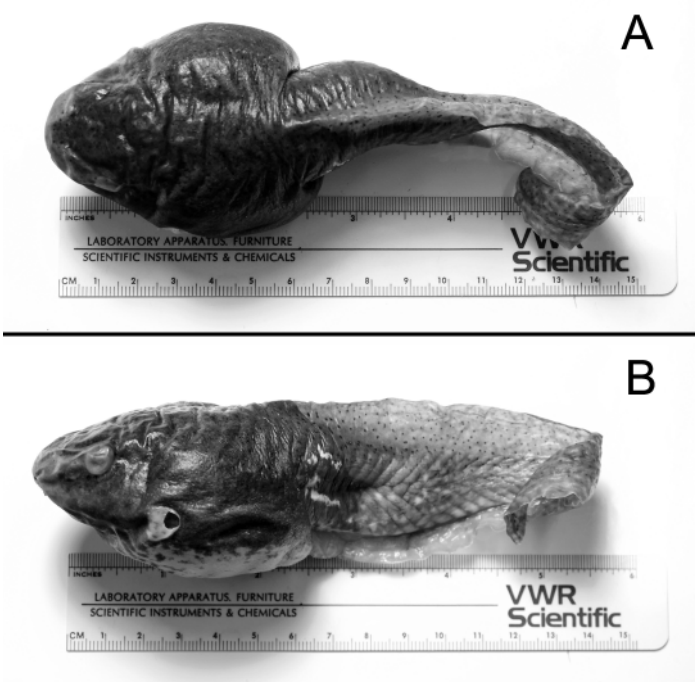

FIG. 1A. Gigantic *Rana catesbeiana* tadpole taken from fish hatchery pond in Cornville, Arizona, USA, Dec 2007. 1B. Metamorphosis appears to have stalled at Gosner Stage 25, as no limb buds are evident.

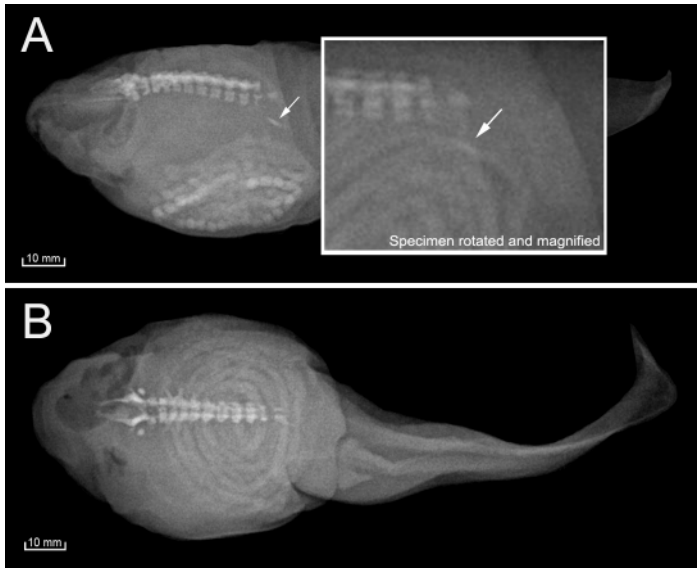

FIG. 2A. Lateral x-ray of gigantic *Rana catesbeiana* tadpole. Arrow indicates a suspected pelvic girdle calcification. Further examination (via rotational x-ray; inset) provided some support that this apparent contrast was actually superimposition of intestinal coils. 2B. Dorsal x-ray.

We thank AZGFD staff F. Agyagos, D. Billingsley, C. Cantrell, C. Dunn, D. Fox, S. Penrod, B. Sisson, and D. Ward for aid in the discovery of this specimen. M. Bolek, O. Hyman, M. Sredl, R. Wassersug, and others provided valuable insight for this manuscript. X-rays were facilitated by S. Logan at the Phoenix Zoo. Digital images were provided by A. Karam.

RANA PRETIOSA (Oregon Spotted Frog). **REPRODUCTION**. Endangered in the state of Washington (Washington Dept Fish and Wildlife 2007. Sensitive species list. WDFW, Olympia), Canada (COSEWIC 2000. Assessment and Status Report on the Oregon Spotted Frog in Canada. Committee on the Status of Endangered Wildlife in Canada, Ottawa. 22 pp.), and a candidate for federal listing in the United States (USFWS 2001. Fed. Reg. 66:1295–1300), *Rana pretiosa* has been a focus of recent study (Hayes et al. 2006a. Herpetol. Rev. 37:209–210; Rombough et al. 2006. Herpetol. Rev. 37:210). Despite significant efforts at quantifying reproduction (Hayes et al. 2006b. Northwest. Nat. 87:171), reproductive behavior, particularly during oviposition, remains undescribed. Hence, we provide a preliminary description of oviposition in *R. pretiosa* from Washington State, USA.

Observations were made during surveys for *R. pretiosa* egg masses on the Troh area of Conboy Lake National Wildlife Refuge (Klickitat Co.) during March 2007 (45.9873°N, 121.2665°W, WGS 84; elev. ca. 555 m). We provided general descriptions of this site elsewhere (Hayes et al. 2006a, *op. cit.*; Rombough et al.

2006, *op. cit.*). The area where these observations were made is a historical oviposition site for *R. pretiosa* at Conboy Lake NWR; calling males and egg masses have been observed annually over the last 10 years.

At 1315 h on 12 March 2007, CJR encountered two pairs of amplectic *R. pretiosa* (Pair 1: female ~88 mm SVL, male ~68 mm SVL; Pair 2: female 86.3 mm SVL, male ~67 mm SVL). Both pairs were on the bottom of 20-cm deep water among clumps of *Carex* in a seasonally flooded meadow, and were sitting next to a freshly laid (< 2 h old) egg mass. The two pairs were facing away from each other, < 8 cm apart. When first encountered, Pair 1 immediately swam beneath the sedges, presumably because of the appearance of CJR, and were not seen again. At the same time, the female of Pair 2 had just begun laying eggs, which were visible as they issued from her body as a mixed black-and-white mass. Based on subsequent observation, the female had extruded about 20% of her eggs when first encountered. Over the next ~2 min, this female laid her remaining eggs in one fluid motion except for the final 10%, which were expelled via a series of short pulses. Based on the rate of oviposition, the entire time required for egg deposition was likely < 3 min. Several seconds after the female had finished laying, the male frog released his hold and floated to the surface, at which point he spotted CJR and swam away. The female, which now had a distinctly baggy appearance, was captured, measured, weighed (37.0 g), and released at the capture site.

As first laid, the egg mass measured ca. 45 × 15 × 15 mm. The embryos were randomly oriented, with the light (vegetal) pole of some eggs positioned upwards. After ca. 30 min, the mass had nearly doubled in volume, to ca. 75 × 30 × 30 mm, and most embryos were re-oriented so that the dark (animal) pole faced upward. After 75 min, the mass measured ca. 95 × 70 × 70 mm, and all of the embryos were now oriented with the animal pole up. By 90 min post-oviposition, the mass was roughly spherical, ca. 100 mm in diameter, and similar in size to the older (now ~3.5 h old) egg mass next to it.

Observations were made within a group of calling male *R. pretiosa*; 12 males were visible within a relatively small (ca. 3 m^2) area. These male frogs were either floating quietly at the water's surface or were calling from either floating or submerged positions. Audible calls consisted of a series of 3–7 (usually 5) note, "knocking" sounds, consistent with that described for the species (Nafis 2006. Sounds of *Rana pretiosa*. online: http://www.californiaherps.com/noncal/northwest/nwfrogs/pages/r.pretiosa.html). At least two other unpaired females, both apparently gravid and measuring ca. 87 and 89 mm SVL, were also present. Unlike the males, which could be approached rather closely (within 1 m and hand captured), these females were wary and dove seconds after seeing CJR.

Few descriptions of oviposition among ranid frogs in a field setting exist. The process we describe here is similar to that seen in *Rana boylii* in that most eggs were extruded at a constant speed over a short time (ca. 1.5 min. for *R. boylii*; Rombough and Hayes 2005. Northwest Nat. 87:157–160) and overall oviposition duration was < 10 min (Wheeler et al. 2003. Herpetol. Rev. 34:234). A brief oviposition interval might be related to deposition of all eggs in one mass (the method of all western North American ranids), as ranid frogs with smaller clutch sizes (than western North American species) which partition their eggs into several packets have longer oviposition intervals (Tsuji and Lue 1998. Copeia 1998:769–773). Further, though the process of egg deposition in the laboratory is well known (Fankhauser 1948. Ann. New York Acad. Sci. 49:684–708; Sype 1975. Breeding Habits, Embryonic Thermal Requirements and Embryonic and Larval Development of the Cascade Frog. Ph.D. Diss., Oregon State Univ., Corvallis. 113 pp.), the post-fertilization reorientation of embryos is almost never reported. Detailed observations are needed to understand variation in the timing of this phenomenon.

Work, conducted under a programmatic permit from the WDFW, adhered to the guidelines for the care and handling of amphibians in the field as detailed in Beaupre et al. (2004. Guidelines for Use of Live Amphibians and Reptiles in Field and Laboratory Research, 2nd ed. HACC, American Society of Ichthyologists and Herpetologists). This is a contribution from the Habitat Program of the WDFW.

SCINAX EURYDICE (Maracas Snouted Treefrog). **PREDATION**. Aquatic invertebrates, especially belostomatids, are often cited as predators of tadpoles (Eterovick and Barata 2006. Herpetologica 62:363–377; Eterovick and Sazima 2000. Amphibia-Reptilia 21:439–461) and adult frogs (Bastos et al. 1994. Herpetol. Rev. 25:118; Brasileiro et al. 2003. Herpetol. Rev. 34:137; Haddad and Bastos 1997. Amphibia-Reptilia 18:295–298; Toledo 2003. Phyllomedusa 2[2]:105–108). *Scinax eurydice* occurs in Brazil from the northern state of Bahia to São Paulo (Ribeiro et al. 2005. Biota Neotropica 5[2]:1–15). This species occurs in open, wet areas, being common in the Atlantic Forest fragments in the municipality of Mariana, Minas Gerais State, southeastern Brazil (43.50025°W, 20.24916°S; WGS 84; ca. 900 m elev). On 24 Jan 2007 at ca. 2200 h we found a female *S. eurydice* (49.6 mm SVL), with eggs inside its oviducts, being preyed upon by the belostomatid, *Lethocerus annulipes* (62.4 mm body length, 25 mm body width). The adult male belostomatid was on the water surface of a temporary pond holding the frog with its raptorial forelimbs. We captured and preserved both animals. *Scinax eurydice* calls and lays it eggs on water bodies that usually have high densities of belostomatids and thus is vulnerable to these aquatic invertebrate predators. The *S. eurydice* (LZV 877) is deposited in the Laboratório de Zoologia dos Vertebrados of Universidade Federal de Ouro Preto, MG, Brazil; the belastomatid (IC 5052) is deposited in the Invertebrate Collection of Universidade Federal de Minas Gerais, MG, Brazil.

Gerais, 30123-970, Belo Horizonte, MG, Brazil; and **FELIPE SÁ FORTES LEITE**,Classe Construções e Meio Ambiente, Rua Almirante Tamandaré, 438, CEP 30430-120, Belo Horizonte, MG, Brazil.

SCINAX GRANULATUS (NCN). **REPRODUCTION**. The reproductive strategy described for the species of the genus *Scinax* agrees with the strategy of most species of Hylinae, which consists of laying egg masses adhered to submerged vegetation (Cei 1980. Amphibians of Argentina. Monitore Zool. Ital., N. S., Monogr. 2. 609 pp.; Gallardo 1987. Anfibios Argentinos. Guía para su Identificación. Biblioteca Mosaico, Bs. As., Agropecuaria 1. 98 pp.; Lavilla and Cei 2001. Amphibians of Argentina A Second Update, 1987–1997. Mus. Reg. Scien. Natur. Torino 28. 177 pp.; Lavilla and Rouges 1992. Reproducción y Desarrollo de Anuros Argentinos. Asociación Herpetológica Argentina 5:1–61; Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill Book Co., New York. 670 pp.). This note describes egg deposition for *Scinax granulatus* in its natural environment.

The observations were made in the vicinity of La Plata city, Buenos Aires province, Argentina (36.0182°S, 57.8591°W; WGS 84) between September 2003 and February 2006 as part of a more comprehensive study of the reproductive behavior of this species. The following description is based on four clutches observed in the field. After oviposition we noted the spatial arrangement of eggs, and counted between 300–700 eggs in each clutch, with pigmented animal pole, 1.3 mm ± 0.04 diameter embryos and 1.7 mm ± 0.05 capsules with jelly coat (mean ± 95% confidence limits, N = 35).

Scinax granulatus disperses its eggs on the bottom of water bodies, and the eggs adhere to submerged objects and/or the bottom individually or in small clusters of 2–3 eggs. The clutches observed were scattered over an average surface area of 3616 cm^2, which represented a small portion of the water body. To our knowledge, this is the first report of this egg deposition mode for a species of Hylinae.

We thank Diego Antonio Rios Barrasso for help with fieldwork.

GASTROPHRYNE PICTIVENTRIS (Nicaragua Narrowmouth Toad), ***HYPOPACHUS VARIOLOSUS*** (Sheep Frog). **ENDOPARASITES.** Herein we report endoparasites of two microhylid frog species from Costa Rica. *Gastrophryne pictiventris* is known from southeastern Nicaragua and the Atlantic slope of Costa Rica; *Hypopachus variolosus* occurs from southern Texas to Costa Rica (Savage 2002. The Amphibians and Reptiles of Costa Rica. A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). We know of no reports on the helminths of these species.

Two *G. pictiventris* adult males (mean SVL = 27 mm ± 1.4 SD, range: 26–28 mm) collected in 1966 from Heredia Province (LACM 155965, 155967) and four *H. variolosus* adult males (mean SVL = 36 mm ± 1.4 SD, range: 35–38 mm) collected in 1963 from Guanacaste Province (LACM 156792–156795) were examined for endoparasites. The frogs were opened by a mid-ventral incision and the lungs, stomach, small and large intestines, urinary bladder, liver, and body cavity were searched for endoparasites using a dissecting microscope. Each nematode was cleared in a drop of glycerol, coverslipped, and studied as a temporary wetmount. The pentastome was cleared in cedarwood oil and studied under a dissecting microscope.

Found in *G. pictiventris* were two species of Nematoda: four *Cosmocerca podicipinus* (mean: 2.0 ± 1.4 SD, range: 1–3) small and large intestines; one *Oswaldocruzia costaricensis* in the small intestine. One Pentastomida nymph was found in the body cavity. Found in *H. variolosus* were two species of Nematoda: 17 *Cosmocerca podicipinus* (mean 5.7 ± 3.2, range: 2–8) in the small and large intestines; three *Oswaldocruzia costaricensis* (mean: 1.5 ± 0.7, range 1–2) in the small intestines. Voucher helminths were deposited in the United States National Parasite Collection, USNPC, Beltsville, Maryland, USA as: *G. pictiventris, Cosmocerca podcipinus* (USNPC 98743), *Oswaldocruzia costaricensis* (USNPC 98744), Pentastomida (USNPC 98745); *H. variolosus, Cosmocerca podicipinus* (USNPC 98758), *Oswaldocruzia costaricensis* (USNPC 98759).

Oswaldocruzia costaricensis was described from *Rana* cf. *forreri* from Costa Rica by Bursey and Goldberg (2005. J. Parasitol. 91:600–605). It has also been found in *Lithobates warszewitschii* and *Lithobates taylori* from Costa Rica (Goldberg and Bursey 2007. Carib. J. Sci. 43:1–10; Goldberg and Bursey 2007. Carib. J. Sci. 43:65–72). *Cosmocerca podicipinus* is a generalist nematode with a wide distribution in Central and South America and has been reported in bufonid, dendrobatid, hylid, leptodactylid, and ranid frogs as well as one bony fish (Goldberg et al. 2007. Comp. Parasitol. 74:327–342). Infection by *Oswaldocruzia* and *Cosmocerca* are direct with no intermediate host involved (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission, CABI Publishing, Oxon, U.K. 650 pp.). With few exceptions, pentastomids mature in reptiles; various vertebrates serve as intermediate hosts and when eggs ingested by an intermediate host hatch the larvae penetrate the intestine to migrate randomly in the body, finally becoming quiescent and metamorphosing into a nymph (Roberts and Janovy 2005. Gerald D. Schmidt and Larry S. Roberts' Foundations of Parasitology, McGraw Hill, Boston.702 pp.) We consider *G. pictiventris* to be an intermediate host for the pentastome; *Cosmocerca podicipinus* and *O. costaricensis* represent new host records for *G. pictiventris* and *H. variolosus.*

We thank Christine Thacker for permission to examine frogs which are part of the Costa Rica Expeditions (CRE) collection donated to LACM in 1998 by Jay M. Savage. Sean Kirk assisted with dissections.

BURSEY,** Pennsylvania State University, Department of Biology, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

TESTUDINES — TURTLES

CARETTA CARETTA (Loggerhead Sea Turtle). **DIGESTION TIME**. Sea turtles feed on a wide variety of food items, depending on the turtle species, growth stage, and other factors. Digestive processes have been investigated largely in the herbivorous Green Sea Turtle, *Chelonia mydas* (Bjorndal 1997. *In* Lutz and Musick [eds.], The Biology of Sea Turtles. CRC Press, Boca Raton, Florida) and these studies are not necessarily applicable for other marine species. Determining digestion time (i.e., the time necessary for natural food items to pass through the gastrointestinal tract) would help in understanding feeding behavior and nutrition in wild turtles. Given the capacity of sea turtles for long-range movement, knowing time and spatial range of turtle feeding is important for interpreting results on diet composition. Further, knowledge of digestion time can help determine how long turtles should be kept in captivity for studies investigating diet through examination of fecal samples.

Until now, few studies have investigated digestion time of Loggerhead Sea Turtles (Birse and Davenport 1987. Herpetol. J. 1:170–175; Peiter 2005. Master's thesis. Bremen University), and mostly in individuals just a few months old, using artificial diets. It is likely that turtle size and prey type can affect digestive functions. For this reason, the present study attempted to provide information on digestion time for medium-sized juvenile Loggerhead Sea Turtles feeding on wild prey.

A total of 30 live turtles caught by trawlers were kept under observation at the WWF's Turtle Rescue Center in Lampedusa Island, Italy (42.67°N, 16.83°E), during May–September 2005. Turtles captured by trawlers are usually healthy and without hooks or lines in the digestive tract (however all turtles were radiographed to ascertain the absence of hooks). Furthermore, bottom trawlers are assumed to catch turtles in the neritic stage, mainly feeding upon benthic prey, which tend to have hard, non-digestible body parts easily recognized in the feces (in contrast to pelagic prey); thus, these turtles are particularly suitable for investigating digestion time by monitoring defecation. Turtles were kept in captivity for a variable period of time and their tanks were checked four times a day for presence/absence of feces. If present, feces were collected and examined to distinguish species ingested in the wild (e.g., gastropods, crabs, sea urchins) from those given as food in captivity (fish). Only feces assumed to be evidence of wild prey were considered in the analysis.

For each turtle we recorded or calculated Curved Carapace Length notch-to-tip (CCL), number of defecations (ND), interval between the arrival at the center and the first defecation (AFD); interval between the arrival at the center and the last defecation (ALD), defecation frequency (DF), calculated as ND/ALD, mean defecation interval (MDI), calculated as (ALD-AFD)/(ND-1) (only for turtles with minimum two defecations), and water temperature.

The mean ND was 2.7 (SD: 1.5; range: 1–6), AFD was 0.7 days (SD: 0.5; range: 0–1.8), DF was 2.6 days^{-1} (SD: 5.7; range: 0.6–32.0), and MDI was 1.1 days (SD: 0.6; range: 0.3–2.2). The mean ALD was 2.4 days (SD: 1.5; range: 0–5.2), which is likely to be an underestimation due to the unknown time lag between the last feeding in the wild and the arrival at the center. For instance, considering the capture at 00.00, ALD would be 2.8 days. This indicates that digestion of benthic prey items such as those found in the corresponding feces (e.g. gastropods, crabs, sea urchins) takes around 2.5–3 days in turtles of the observed size (mean: 60.2 cm CCL; SD: 9.4; range: 41–80.3) and at the observed temperature (mean 25.0°C; SD: 2.0; N = 21).

Result indicate that feces collected in captivity from turtles caught in the wild, and specifically turtles feeding upon benthic prey, probably correspond to several different meals spanning a period of 2–3 days. This is significant for studies that investigate diet through fecal collection or necropsy, suggesting that such samples can provide good information on the diet covering multiple meals during movement among different sea bottom types. Moreover, maximum ALD suggests that studies investigating diet through fecal samples should keep turtles under observation for a period of at least six days to collect the entire gut content.

This study was possible thanks to the fishermen who collaborated with the WWF Italy's Turtle Center in Lampedusa and to the volunteers who helped with the research.

CARETTA CARETTA (Loggerhead Sea Turtle). **PREDATION**. Sea turtle hatchlings are eaten by a variety of predatory fishes while departing from natal beaches. However, observations beyond the near shore zone are sparse because post-hatchling stages in offshore habitats are cryptic while hiding among *Sargassum* rafts or in drift line debris at current boundaries. Herein, we report a predation event by an endangered fish species upon a threatened turtle species, which involved a juvenile Loggerhead Sea Turtle (*Caretta caretta*) eaten by a Goliath Grouper (*Epinephelus itajara*) off the southwestern Florida coast.

On 14 December 2006, the crew of the R/V Eugenie Clark retrieved a drum line during surveys for large coastal sharks conducted by the Center for Shark Research at Mote Marine Laboratory. The drum line was 13 km offshore from Sarasota, Florida, USA (27.1470°N, 82.6150°W) in depths of about 12 m. Mid-water column temperature was 18.8°C and salinity was 36.0 ppt. The retrieved line yielded a *E. itajara* (length = 1.7 m) which upon its ascent regurgitated a partly digested but intact *C. caretta* carcass. The turtle specimen was photographed from dorsal, ventral, and lateral aspects adjacent to a landing net of known diameter. The photos provided multiple diagnostic features (number and color of costal scutes, inframarginal pores, carapace shape, and cranial scales) even though the flesh and muscle tissue were partially digested. Image measurements of the landing net compared to the turtle gave an estimate of 30–35 cm straight carapace length. Due to permit restrictions, the turtle carcass was not collected and was returned to the water. The grouper was de-hooked and also released in good condition.

The event is noteworthy given the paucity of information regarding grouper predation on young sea turtles. Groupers

reportedly consume Hawksbill Sea Turtles (*Eretmochelys imbricata*) in the West Indies (Randall 1967. Studies Trop. Ocean., Univ. Miami No. 5:665–847) and Green Sea Turtles (*Chelonia mydas*) in Hawaii (Balazs 1984. Univ. Hawaii Sea Grant Misc. Rep. 84-01(Vol. II), 321 pp.), the Kingdom of Tonga (Witzell 1981. Bull. Mar. Sci. 31:935–936), and the Great Barrier Reef in Australia (Gyuris 1994. Coral Reefs 13:137–144). However, studies of grouper species of the Florida Gulf coast have not yet reported sea turtles in the diet (Bullock and Smith 1991. Mem. Hourglass Cruises, Vol. 8, Pt. 2, 243 pp.) and studies of predators of Florida Atlantic coastal Loggerhead Sea Turtle hatchlings do not record this grouper species (Whelan and Wyneken 2007. Copeia 2007:745–754).

Both *E. itajara* and *C. caretta* receive protection from state and federal agencies within the United States. Recent assessments for *E. itajara* have suggested that the Gulf of Mexico populations may be recovering. This predatory event raises a question as to whether recovery of one protected species might be impacting the recovery of its prey, also a protected species, since top-down trophic cascades can occur in marine ecosystems. The observation also suggests that *E. itajara* in Florida waters are, at the very least, opportunistic consumers of juvenile sea turtles.

We thank staff and interns aboard the R/V Eugenie Clark, and J. Schmid and J. Wyneken for species confirmation.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **COYOTE PREDATION.** Hatchling and juvenile *Gopherus polyphemus* are known to have many predators, including mesomammalian, ophidian, raptor, and invertebrate species (see Epperson and Heise 2003. J. Herpetol. 37:315–324, and references therein). However, known published accounts of predation on adult *G. polyphemus* are limited to Dog (*Canis familiaris*) attacks (Douglass and Winegarner 1977. J. Herpetol. 11:236–238; Causey and Cude 1978. Herpetol. Rev. 9:94–95). Here I report an incidence of a Coyote (*C. latrans*) depredating an adult *G. polyphemus*.

On 15 June 2007 at 1225 h, I arrived at artillery firing point 136 on the Camp Shelby Joint Forces Training Center, Perry County, Mississippi, USA to search for Gopher Tortoise nests. Upon exiting the vehicle, I heard crunching noises coming from the edge of the field, and approached slowly to investigate. When I got within ca. 30 m of the disturbance, I scared off an adult *C. latrans* that had been eviscerating an adult female *G. polyphemus*. The Coyote had ripped open a large hole in the plastron, and had removed the tail and most of the intestines (Fig. 1). The head, limbs, and carapace were all intact, and the damage was presumably done immediately prior to my arrival, since I could see the tortoise's heart still beating. The tortoise died 10 minutes later. I examined all nearby burrows, and did not find any signs of excavation, nor did I find signs of attempted or interrupted oviposition; therefore I assumed that this tortoise had been attacked while out of its burrow. This supports observations by R. E. Ashton (unpubl. data, in Mushinsky et al. 2006. *In* P. A. Meylan [ed.], Biology and Conservation of Florida Turtles, pp. 350–375. Chelonian Research Monographs No. 3) that Coyotes will wait

FIG. 1. Remains of an adult female *Gopherus polyphemus*, eviscerated by a coyote (*Canis latrans*) at the Camp Shelby Joint Forces Training Center, Perry County, Mississippi.

until a Gopher Tortoise leaves its burrow before attacking it. This particular tortoise had been measured the previous summer, and at 283 mm carapace length and a weight of 4.4 kg, it exceeded the averages for adult female *G. polyphemus* at Camp Shelby (ca. 267 mm carapace length and 3.8 kg; N = 281).

Coyotes have been expanding their range across the southeast for decades, partially due to releases by man and extirpation of native predators (Hill et al. 1987. Wildl. Soc. Bull. 15:521–524; Lovell et al. 1998. Wildl. Soc. Bull. 26[3]:552–556). An analysis of annual predator harvest data in Mississippi (Lovell et al., *op. cit*.) found that the numbers of Coyotes increased 7.5-fold from 1980 to 1995 (unlike Bobcat, Red Fox, and Grey Fox numbers, which remained relatively unchanged during that same period). The increased numbers of Coyotes in the area represent a relatively new predation pressure for *G. polyphemus*, adding to the growing list of threats (including habitat conversion and fire exclusion) already facing this federally-protected species.

Submitted by **MATTHEW G. HINDERLITER**, Camp Shelby Field Office, The Nature Conservancy, CSJFTC-ENV Building 622, Camp Shelby, Mississippi 39407, USA; e-mail: mhinderliter@tnc.org.

HYDROMEDUSA MAXIMILIANI (Brazilian Snake-necked Turtle)**. HATCHLING SIZE AND BODY MASS.** The chelid turtle *Hydromedusa maximiliani* is endemic to eastern and southeastern Brazil (Minas Gerais, Espírito Santo, Rio de Janeiro, and São Paulo states) and in parts of southern Bahia, and is associated with mountainous regions (Souza 2004. Reptilia 53:51–55). On 30 May 2005 at 1100 h we hand-captured, measured, and released one post-hatchling juvenile *H. maximiliani* in Reserva Biológica Muncipal Santa Cândida (21.6888889°S, 43.3444444°W; 770 m elev.), Juiz de Fora, Minas Gerais state, Brazil. The carapace length (CL) of this juvenile was 43 mm, plastron length (PL) was 28.5 mm, and the body mass was 7.8 g. Guix et al. (1992. Bol. Assoc. Herpetol. Esp. 3:23–25) reported the minimum CL of one (presumably post-hatchling) specimen as 40 mm, but did not provide data on body mass. The minimum body mass for a juvenile *H. maximiliani* previously reported was

15 g (Souza. 1995. Herpetol. Rev. 26:34), though the CL of this specimen was 47.3 mm. The specimen here reported, probably a recent post-hatchling, represents a new record for minimum body mass and plastron length for a juvenile *H. maximiliani*.

This work was licensed by IBAMA (Process nº 02015.003546/04-11), and was performed under the principles adopted by COBEA (Brazilian School of Animal Experimentation), which were approved by the Committee of Ethics in Animal Experimentation (Pro-Rectory of Research) of the Universidade Federal de Juiz de Fora, in a meeting which took place on 04/12/2004 (Protocol nº 011/2005-CEA).

We thank CNPq and Samuel Campos Gomides, Aline de Oliveira Santos, and Juliane Floriano Lopes for logistical support.

Submitted by **IARA ALVES NOVELLI** (e-mail: iaranovelli27@gmail.com), and **BERNADETE MARIA DE SOUSA** (e-mail: bernadete.sousa@ufjf.edu.br), Laboratório de Herpetologia, Departamento de Zoologia, Instituto de Ciências Biológicas, Universidade Federal de Juiz de Fora, Campus Universitário, Bairro Martelos, Juiz de Fora, MG, Brazil, 36036-330.

HYDROMEDUSA MAXIMILIANI (Brazilian Snake-necked Turtle)**. DIET.** Adult *Hydromedusa maximiliani* are primarily carnivorous, feeding on aquatic invertebrates, including insect larvae and crustaceans (Souza 2004. Reptilia 53:51–55; Souza and Abe 1995. Chelon. Conserv. Biol. 1:320–322; Souza and Abe 1998. J. Herpetol. 32:106–112). This diet is complemented by terrestrial invertebrates that fall into the water, anurans, and carrion (Souza 2004, *op. cit*.). Here we report on *H. maximiliani* feeding on *Trichodactylus fluviatilis*, a freshwater decapod native to South America.

We gathered data on the feeding habits of *H. maximiliani* from October 2004 to May 2005, in the Reserva Biológica Municipal Santa Cândida (21.6888889°S, 43.3444444°W; 770 m elev.), Juiz de Fora, Minas Gerais state, Brazil. The stomach contents of 10 specimens of *H. maximiliani* were sampled by flushing (Legler 1977. Herpetologica 33:281–284). The decapod was identified in accordance with Magalhães (2003. *In* Melo [ed.], Manual de Identificação dos Crustáceos Decápodos de Água Doce do Brasil, pp. 143–287. São Paulo, Edições Loyola). Six samples of stomach contents revealed parts of the carapace, pereiopod, and cheliped of *T. fluviatilis*. Freshwater decapods previously reported as prey of *H. maximiliani* are *Aegla odebrechi*, *A. paulensis*, and *Hyalella pernix* (Yashimita 1990. Herpetol. Rev. 21:19; Souza and Abe 1995, *op. cit*.; Souza and Abe 1998, *op. cit*.; Souza and Abe 1997. Bol. Asoc. Herpetol. Esp. 8:17–20). This is the first report of *T. fluviatilus* being consumed by *H. maximiliani*.

We thank Célio Magalhães Ubirajara Filho of the Instituto Nacional of Pesquisas of Amazônia (INPA) for confirmation of the decapod species.

KINOSTERNON SONORIENSE (Sonoran Mud Turtle). **DIET.** *Kinosternon sonoriense* is generally considered a carnivore, but occasionally consumes plant material when benthic fauna are limited (Hulse 1974. J. Herpetol. 8:195–199). Over the last decade, we have documented several observations of Sonoran Mud Turtles feeding on vertebrates in ephemeral canyon pools in the Peloncillo Mountains, Hidalgo Co., New Mexico (Ligon and Stone 2003. Herpetol. Rev. 34:241–242*;* Stone et al. 2005. Herpetol. Rev. 36:312). Here, we add the House Finch (*Carpodacus mexicanus*) to the list of vertebrate species *K. sonoriense* has consumed in this setting. On 17 July 2007, ca.1200 h, we approached an isolated canyon pool (ca. 20 cm in depth and 1.5 m^2 in area) and observed a dead House Finch floating near the edge. Just before we began to search the pool, we noticed the dead bird gently rippling on the surface. We examined the bird and noted its breast and belly were missing and much of the sides and flanks had been picked clean of meat, with only the head, wings, and legs remaining intact. A female *K. sonoriense* (MCL = 100.8 mm) was found on the bottom of the pool directly underneath the bird. After identifying and measuring the turtle, we placed the turtle and bird back into the pool and then quietly waited and observed. After a few minutes the bird again began to gently ripple, presumably due to the turtle feeding on the carcass.

Stone et al. (2005, *op. cit.*) reported a similar observation involving a Mockingbird (*Mimus polyglottus*), and Ligon and Stone (2003, *op. cit.*) reported two instances of Sonoran Mud Turtles feeding on toads (*Bufo punctatus*). These are the only birds and only anurans we have found dead in canyon pools during a long-term field study (Stone 2001. Southwest. Nat. 46:41–53). Stone et al. (2005, *op. cit.*) also observed a Sonoran Mud Turtle kill and eat a garter snake (*Thamnophis cyrtopsis*). Although observations involving birds and anurans could represent instances of scavenging, the accumulated observations suggest that *K. sonoriense* opportunistically preys on vertebrates in canyon pools. Regardless, it is clear that canyon pools provide unique feeding opportunities for Sonoran Mud Turtles, and that vertebrates likely comprise a more significant portion of this species' diet than previously reported.

We thank the College of Graduate Studies and Research at the University of Central Oklahoma for financial support. This study was conducted under permits issued by the New Mexico Department Game and Fish (Permit No. 2905) and the U.S. Forest Service (Authorization ID: SUP0800).

CROCODYLIA — CROCODILIANS

CAIMAN CROCODILUS **(**Spectacled Caiman**). OPPORTUNISTIC FORAGING.** We document opportunistic foraging behavior by *Caiman crocodilus* in a post-inundation

forest at Estacíon Biologíca Caño Palma, Costa Rica. Estacíon Biologíca Caño Palma is a 40-ha reserve located on the northeast coast of Costa Rica, south of Barra del Colorado. This reserve and the surrounding area is lowland tropical wet forest (*fide* Holdridge 1967. Lifezone Ecology, Tropical Science Center, San José, Costa Rica. 206 pp.) comprised predominantly of *Manicaria* swamp forest (Myers 1990. *In* Lugo et al. [eds.], Ecosystems of the World, pp. 267–278. Elsevier, Oxford, UK, 527 pp.). Bounded by large catchment rivers to the north, south, and west with a blackwater channel to the east, the forest inundates seasonally (November–December and May). *Manicaria* forests typically exhibit a prominent bi-annual polymodal inundation during the wettest season (Junk et al. 2000. The Central Amazon floodplain: Actual Use and Options for a Sustainable Management. Backhuys Publishers, Leiden, Holland. 584 pp.). The seasonal inundation event that engulfs Estacíon Biologíca Caño Palma is also coupled with local tidal flow patterns (Kelso 1967. A Contribution to the Ecology of a Tropical Estuary. M.Sc. Thesis, Univ. Florida, Gainesville. 156 pp.). Once inundation subsides, numerous temporal pools remain in the forest; these generally disappear during the warmer (and drier) months of the year.

In December 2002 and again in January 2004, during three months of weekly diurnal visual-encounter transects of post-inundation *Manicaria* forest, 5 adult and 7 juvenile caiman (2002) and 4 adult and 3 juvenile caiman (2004) respectively were located well into (often > 100 m) the forest. Once disturbed, they retreated terrestrially toward the channel associated with riparian habitat, rapidly slipping in and out of temporary pools as they headed in an easterly direction toward the main blackwater channel bordering the property.

Caiman reproduction, which generally occurs during the rainy season in this region of Costa Rica (November–February), involves construction of vegetation mounds in forested environments to incubate their eggs (Allsteadt 1994. J. Herpetol. 22:12–19.). As in other crocodilians, caiman exhibit well-developed parental care and will defend nests from predators, the primary threat to their eggs (Leenders 2001. A Guide to Amphibians and Reptiles of Costa Rica. Zona Tropical, Miami, Florida. 305 pp.). We detected no evidence of nests or nest-guarding behavior in the areas where we sighted caiman. However, these areas, still saturated by water, were found to frequently be full of suffocating fish trapped in desiccating flood pools or anurans utilizing these ponds for breeding. Fish species present included: *Archocentrus nigrofasciatus* and *Parachromis managuensis* (Cichlidae), *Rhamdia guatemalensis* and *Rhamdia rogersi* (Pimelodidae), and *Astyanax aeneus* (Characidae). *Atractosteus tropicus* (Order: Semionotiformes) were also hunting in these pools and may have constituted prey. That caiman were feeding on the diverse prey within these seasonally restricted environments seems likely. Fish are an important prey species for many crocodilians (Magnusson 1987. J. Herpetol. 21:85–95) and can make up over 25% of total prey items in sub-adult and mature adult caiman (Thorbjarnarson 1993. Herpetologica 49:108–117; Velasco et al. 1994. Crocodile Specialist Group Newsletter 13:20–21). In tropical blackwaters Cichlidae, Pimelodidae, and Characidae can make up 10–27% of the composition of fish species consumed (Thorbjarnarson 1993, *op. cit.*; Santos et al. 1996. Herpetol. J. 6:111–117) and possibly more when increases in water level like that which occurred along the Caño Palma allow more fish access to greater volumes of water and increased predation susceptibility (Silveira and Magnusson 1999. J. Herpetol. 33:181–192).

Caiman now occur in diverse habitats such as marshes, rivers, channels, and lakes in both the Caribbean and Pacific lowlands of Costa Rica, particularly as a result of the now-diminished ranges of sympatric competitors (*Crocodylus acutus*) (Magnusson 1982. Proc. 5th IUCN/SSC Croc. Spec. Group, pp. 108–116. Gland, Switzerland). They are commonly found in the canals, dikes, and channel networks in forested floodplain habitats (Allsteadt and Vaughan 1992. Brenesia 38:65–69; Guyer 1994. *In* McDade et al. [eds.], La Selva: Ecology and Natural History of a Neotropical Rain Forest, pp. 210–216. Univ. Chicago Press, Chicago, Illinois; Guyer and Donnelly 2005. Amphibians and Reptiles of La Selva, Costa Rica and the Caribbean Slope. Univ. California Press, Berkeley, California. 299 pp.; Ouboter and Nanhoe 1988. J. Herpetol. 22:283–294; Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Illinois. 934 pp.). This species is known to establish territories in local channel networks where they exhibit high site tenacity (Savage 2002, *op. cit.*), especially in areas that provide a sustainable food resource. Opportunistic seasonal shifts in habitat use has not been widely reported in *Caiman crocodilus*. Our observations imply that these habitat shifts provide enhanced feeding opportunities that might be unavailable the rest of the year. We present two models that might explain these habitat shifts. In the first, caiman might periodically abandon their territories within the permanent channel network during episodic inundation to specifically forage for trapped fish within temporary pools in the forest. The second model proposes that caiman, along with other fauna, advance into the forest during inundation following the expanding shoreline. As the water recedes, some aquatic animals are trapped in pools where they are vulnerable to amphibious predators, such as caiman. Caiman are able to escape back to traditional channel-margin habitat as the pools disappear. Which is correct provides an interesting question for further research.

We thank The Canadian Organization for Tropical Education and Rainforest Conservation for permission to study at Caño Palma Biological Station, Xavier Guevara of the Ministerio de Recursos Naturales Energia y Minas for permitting licenses, and Farnborough College of Science and Technology for assistance.

CROCODYLUS MORELETII (Morelet's Crocodile). **SALINITY TOLERANCE**. Salinity and temperature are the major abiotic factors limiting crocodile distribution and abundance (Duson and Mazzotti 1989. B. Mar. Sci. 44:229–244; Mazzotti et al. 2007. J. Herpetol. 41:122–132; Richards et al. 2004. Ecol. Model. 180:371–394). *Crocodylus moreletii* lacks excretory (salt)

glands, so it is typically considered freshwater-dwelling (Platt and Thorbjarnarson 2000. Biol. Conserv. 96:21–29). Hence, here we provide observations indicating that *C. moreletii* may be more salinity tolerant than previously recognized.

During nocturnal crocodile surveys of La Mancha Lagoon, Veracruz, Mexico (19.5689°N, 96.3872°W; datum: NAD27; elev. 0 m.) in March 2007, we recorded the size range of *C. moreletii* in relation to water salinity. We measured salinity using a multi-parameter YSI85. Following Platt and Thorbjarnarson (*op. cit.*), we classified crocodiles based on total length (TL) as hatchlings (TL < 29.9 cm), yearlings (TL = 30–50 cm), juveniles (TL = 51–100 cm), subadults (TL = 101–150 cm), and adults (TL > 150 cm). We observed 10 crocodiles, four yearlings, three juveniles, two subadults and one adult. Hatchlings were observed in 3.4 parts per thousand (ppt), juveniles in 10.8 ppt, subadults in 22.7 ppt, and adults in 21.4 ppt.

Taplin (1988. Biol. Rev. 63:333–377) suggested that *C. moreletii* tolerantes heavily brackish water (> 20.0 ppt). However, in coastal Mexico and Belize where Morelet's and American crocodiles (*C. acutus*) occur in macrosympatry, the former is generally confined to freshwater, whereas the latter is found in saline habitats (Cedeño-Vázquez et al. 2006. Herpetol. Nat. Hist. 10:17–30). Our observations compliment the earlier report of Meerman (1992. Occ. Pap. Belize Nat. Hist. Soc. 1:1–5) from Chetumal Bay where fisherman captured an adult *C. moreletii* in heavily brackish water (22 ppt). Collectively, these data suggest that *C. moreletii* is physiologically capable of tolerating moderately saline conditions. Hence, its general absence from brackish coastal habitats may arise from conditions other than a limiting saline environment, such as those resulting from the poorly understood interspecific interactions with *C. acutus*.

RHYNCHOCEPHALIA — TUATARAS

SPHENODON PUNCTATUS (Common Tuatara). **PREY DETECTION.** *Sphenodon punctatus* are generally regarded as nocturnal visual hunters that rely on movement to detect and capture prey (Dawbin 1962. Endeavour 21:16–24; Walls 1981. New Zealand J. Ecol. 4:89–97). They feed primarily on orthopterans, beetles, and arachnids (Ussher 1999. New Zealand J. Zool. 26:117–125), but are also known to eat the eggs (Gaston and Scofield 1995. Notornis 42:27–41) and chicks (Walls, *op. cit.*) of Fairy Prions (*Pachyptila turtur*), small burrowing seabirds that occur at high densities on many *S. punctatus*-inhabited islands. As *S. punctatus* and *P. turtur* often use the same burrows (Newman 1987. Herpetologica 43:336–344), *S. punctatus* are likely to occasionally encounter prion chicks when entering a burrow, and they may opportunistically consume them as well as any eggs present in the burrow. However, in the absence of movement cues, detection of certain food items such as carrion or isolated eggs may be more readily accomplished via olfaction (Walls, *op. cit.*). Here we report an observation of a male *S. punctatus* feeding on a *P. turtur* egg during which time it displayed behavior consistent with olfaction.

At ca 1200 h on 28 November 2006, an intact *P. turtur* egg was observed on a concrete slab at the base of a small bank on Stephens Island, Cook Strait, New Zealand (40.67°S, 174.00°E; elev. 215 m). The egg had likely been laid in one of the burrows dug into the side of the bank, and may have been displaced by the burrowing activity of a *S. punctatus* or seabird, whereupon it rolled out of the burrow and onto the slab. Though the eggshell was intact, it had evidently not been viable for some time as its odor was easily detectable to human observers. Importantly, we observed no flies near the egg at this point. At 1400 h, a male *S. punctatus* was observed and video-recorded consuming the egg. He broke the eggshell in his jaws and then proceeded to chew up and swallow the shell fragments. During this process, yolk dripped onto the concrete slab and spread out in a thin layer over about 5 cm^2, attracting numerous flies that swarmed around the yolk and the face of the *S. punctatus*. After having eaten all of the shell fragments, the *S. punctatus* proceeded to probe at the ground with his snout and the tip of his lower jaw and appeared to be searching for additional matter that could be consumed. He probed first in the vicinity of the spilled yolk, and then moved in a zig-zag pattern, first outward from the yolk and then down the side of the concrete slab, before returning to probe again at the site of the yolk. The nose-probes were interspersed by motions in which the *S. punctatus* dragged his snout along the ground without breaking contact with the substrate. At no point did he display any tongue-flicking or mouth-opening behavior consistent with vomeronasal detection. In addition, the flies attracted to the broken egg were landing on the spilled yolk but not the surrounding area, and a search pattern by the *S. punctatus* based on the movement of the flies should have kept his attention on the flies at the spilled yolk. Instead, upon consuming the last of the eggshell, the *S. punctatus* searched the area independently of the location of the flies. Moreover, the *S. punctatus* immediately swatted with a forelimb at any flies that landed on his face, even during an agonistic encounter with an approaching male conspecific. The *S. punctatus* remained in the vicinity for ca. 35 min.

Although *S. punctatus* are active primarily at night, they spend much of the day basking at their burrow entrances (Goetz and Thomas 1994. New Zealand J. Zool. 21:473–485; Walls 1983. New Zealand J. Zool. 10:309–318). As sit-and-wait predators, it is not surprising that they would also feed during the day if the opportunity arose, as it did in this observation. The behavior displayed here is consistent with prey detection via olfaction because we could identify no movement cues at the time the prey item was first detected by the *S. punctatus*; subsequent motion by flies was ignored; and the *S. punctatus*'s probing was consistent with olfactory, but not vomeronasal, detection.

SQUAMATA — LIZARDS

ANOLIS UNIFORMIS (Lesser Scaly Anole). **DIET.** *Anolis uniformis* is a small lizard widely distributed in wet tropical rain forests from southern Tamaulipas, México through northern Guatemala and Belize to northern Honduras. It occurs in forest understory from near sea level to about 900 m (Campbell 1998. Amphibians and Reptiles of Northern Guatemala, the Yucatán, and Belize. University of Oklahoma Press, Norman, Oklahoma. 380 pp.; Campbell et al. 1989. Biotropica 21:237–243; Lee 1996. The Amphibians and Reptiles of the Yucatan Peninsula. Comstock Publishing Associates. Cornell University Press, Ithaca, New York. 500 pp.). The most observable lizard at Los Tuxtlas tropical rain forest, Veracruz, México, *A. uniformis* is thought to be a diurnal insectivore across its geographic range (Duellman 1963. Univ. Kansas Publ. Mus. Nat. Hist. 15:205–249; Villarreal 1997. *In* González et al. [eds.], Historia Natural de los Tuxtlas, pp. 495–500. Universidad Nacional Autónoma de México, México, D.F.; Villarreal and Heras 1997. *In* González et al. [eds.], *op. cit*., pp. 476–478). Here we report predation by *A. uniformis* on an anuran.

At 2315 h on 3 September 2003 during a nocturnal herpetofaunal survey, we observed a young male *A. uniformis* (29 mm SVL) swallowing a very small (ca. 9 mm SVL) leaf litter frog (*Craugastor* sp.). The event occurred on the leaf of a medium-sized plant in a small bamboo and tropical rain forest remnant in the Los Tuxtlas region, Veracruz, México (18.6072°N, 95.1437°W; datum: WGS84; elev. 650 m). The anole was collected and deposited in Colección Nacional de Anfibios y Reptiles, Instituto de Biología, Universidad Nacional Autónoma de México (CNAR IBH 21138).

From September 2006 to July 2007, we also collected and dissected 30 *A. uniformis* adults at the Laguna Escondida rainforest remnant at Los Tuxtlas region (18.5909°N, 95.0883°W; elev. 150 m) as a part of a parasitological study. Examination of stomach and intestinal contents revealed only arthropod remains, mostly terrestrial and flying insects (flying Diptera, Hymenoptera, Hemiptera; terrestrial Orthoptera) and a few spiders. We found no amphibian remains in this sample.

Previous diet records for *Anolis uniformis* (Stuart 1948. Misc. Publ. Mus. Zool. Univ. Michigan 69:1–109; Villarreal, *op. cit.*; Villarreal and Heras, *op. cit.*) indicate that it preys on insects and litter-dwelling invertebrates, especially soft-bodied arthropods. Our 2003 observation indicates that *A. uniformis* can prey on small amphibians and that it may sometimes feed at night.

We thank to F. Bertoni, M. Márquez, R. Paredes, H. Reyes, and M. Sánchez for assistance in the field.

Submitted by **ELISA CABRERA GUZMÁN** and **VÍCTOR HUGO REYNOSO,** Colección Nacional de Anfibios y Reptiles. Instituto de Biología. Departamento de Zoología, Universidad Nacional Autónoma de México. Circuito exterior, Ciudad Universitaria. México D.F., C.P. 04510 (e-mail: anfisbenido@yahoo.com).

CTENOSAURA PECTINATA (Spiny-tailed Iguana). **POPULATION STATUS**. *Ctenosaura pectinata* is native to the west coast of Mexico and ranges from mid-Sinaloa to south Oaxaca, at elevations below 1000 m (Burghardt and Rand 1982. Iguanas of the World: Their Behavior, Ecology, and Conservation. Noyes Publ., Park Ridge, New Jersey. 504 pp.). During the last century, *C. pectinata* was introduced into Brownsville, Texas as well as south Florida (Conant and Collins 1998. A Field Guide to the Reptiles and Amphibians, Eastern / Central North America. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). Both populations have been established for nearly 40 years (Smith and Kohler 1978. Trans. Kansas Acad. Sci. 80:1–24; Meshaka et al. 2004. Exotic Amphibians and Reptiles of Florida. Krieger, Malabar, Florida. 155 pp.). The population in south Florida has been discussed in the literature numerous times (see Meshaka et al., *op. cit*. for a review) but little has been published about the Brownsville population. Here, we document the persistence of *C. pectinata* in Brownsville and their use of artificial microhabitat.

From 6–16 June 2007, we conducted eight searches for *C. pectinata* at the Gladys Porter Zoo (GPZ), Brownsville, Texas, USA (97.4952°W, 25.8831°N; datum: WGS84; elev. 6 m) and vicinity. Searches were conducted between 0800–1400 h, when iguanas would be basking. We searched the GPZ by slowly walking along exhibits, alleys, and buildings for ca. 3 h during each search. We also chose areas of the surrounding neighborhood that were within 0.5 km of the GPZ, and searched them by slowly walking along sidewalks and alleys for ca. 1 h. We used binoculars and digital photo equipment to find, observe, and record observations of *C. pectinata.* Photos and videos were reviewed to distinguish multiple sightings of an individual from sightings of several individuals based on coloration, markings, and head shape. Captures could not be made due to facility restrictions. We used a Garmin eTrex Vista C GPS unit to georeference *C. pectinata* locations (accurate to within ~5 m). GPZ staff assisted us in locating areas where *C. pectinata* were known to occur.

Though the GPZ staff has received reports of *C. pectinata* elsewhere in south Texas, the only known breeding population is centered at the GPZ in Brownsville. The GPZ (est. 1971) is a 10.5-ha facility dominated by open-area exhibits bordered by fences and artificial rivers and lagoons, and interconnected by artificial rock walls and sidewalks. Nine islands, some with artificial rock structures, have been built to exhibit zoo animals.

Reviews of photographs, videos, and GPS waypoints revealed a total of nine adult (ca. 1 m TL) *C. pectinata* and one juvenile (ca. 20 cm TL) within the zoo grounds. These individuals were located near or inside exhibits that were bordered with artificial

rock walls (2–4 m in height); three adults were observed entering holes in these structures. On 8 June, we observed an adult perched 3 m up on a rocky peak within an exhibit (Fig. 1, pt 1). On 9 June, we observed an adult and a juvenile perched less than 3 m apart on an artificial rock wall in the rear of the same exhibit, shaded by vegetation (pt 2). On 9 June, we also observed an adult entering a hole in the wall, behind an exhibit (pt 3). On 9 June, we observed an adult basking on a level rock surface that was elevated 2 m above an artificial lagoon within a different exhibit (pt 4). This adult was again observed on 15 June, emerging from a crack in the concrete surface of the exhibit floor, 20 m from where it was previously observed (pt 5). On 12 June, two adults were observed simultaneously occupying the same large (4 m × 4 m × 7 m) rock structure on an island (pt 6). These iguanas were separately observed on 6, 10, and 15 June occupying the same structure. On 16 June, we observed two other adults, one missing half its tail, perched within 2 m of each other, on a rocky peak (2.5 m) that was shaded by vegetation (pt 7). This peak was part of a wall separating two exhibits. On 16 June, we observed an adult perched 4 m up on a rock wall within a different exhibit (pt 8).

Two individuals were also observed outside the zoo. One (ca. 0.5 m TL) was observed on Belvedere Drive, a road that separates the zoo from the surrounding neighborhood (pt 9). This individual fled into the zoo as our vehicle approached. The total length and bright green tail coloration indicated that it was a juvenile. The other individual (ca. 0.5 m TL) was observed in a grassy neighborhood alley, ca. 60 m from the zoo (pt 10). This individual was predominantly green, and due to the similarity between hatchling *C. pectinata* and *Iguana iguana*, could have been an *I. iguana*. GPZ staff have observed at least 5 juveniles in the zoo over the past three years, including an individual that was ca. 20 cm TL, seen on 30 June 2007 in an exhibit barn.

Though the population at GPZ has been established for nearly 40 years, we found few individuals (N = 12) despite intensive search efforts. Apparently, population growth has been limited, possibly by low overwinter survival, predation, or both. The lowest average annual minimum temperature (i.e., the coldest temperature experienced each winter) for extreme south Texas for the period 1960–1990 was –1.8°C to –3.8°C (Cathey and Jordan 2001. USDA Plant Hardiness Zone Map. U.S. National Arboretum, Agricultural Research Service, USDA, Washington, DC). In contrast, the lowest average annual minimum temperature for the native range of *C. pectinata* ranged from 1.7°C to about 4.5°C during the period 1960–1990 (Cathey and Jordan 2001, *op. cit.)*, thus, the colder temperatures in south Texas may have affected survivability. Some authors (e.g., Iverson 1978. Biol. Conserv. 14:63–73) have also suggested that predation by cats and dogs may cause populations of ground-dwelling iguana species to decline. Cats and dogs are infrequently encountered inside the GPZ, but their predation could potentially limit populations in surrounding neighborhoods. Besides these potential predators, the GPZ has a large, diverse avian community; birds such as egrets (free-ranging) and hornbills (exhibited) may also be potential predators.

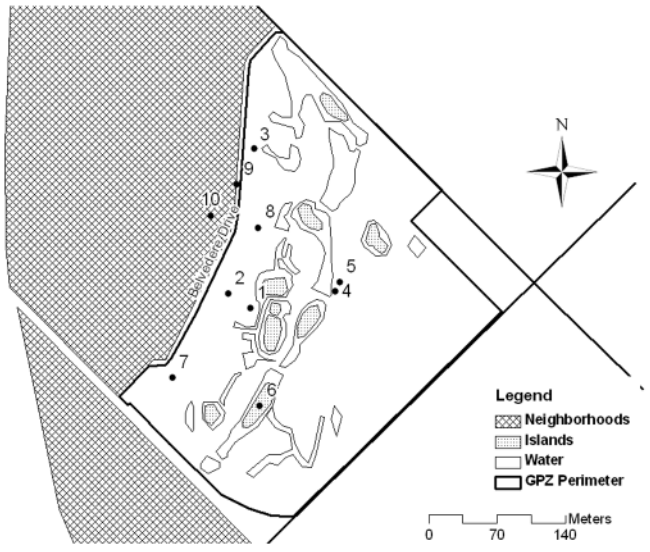

FIG. 1. Map of the Gladys Porter Zoo. Numbered points correspond to sightings of *Ctenosaura pectinata* referred to in the text.

BUTLER** (e-mail: cbutler11@ucok.edu), Department of Biology, University of Central Oklahoma, Edmond, Oklahoma 73034, USA; and **DAVID L. MARTIN**, Department of Herpetology, Gladys Porter Zoo, Brownsville, Texas 78520, USA (e-mail: dmartin@gpz.org).

GLAPHYROMORPHUS NIGRICAUDUS (NCN). **PREY PIRACY.** Prey piracy, the opportunistic theft of prey from another predator or another indirect source, is known for a broad range of diurnal reptilian taxa. In this note I report on an incidence of prey piracy in the skink *Glaphyromorphus nigricaudus*.

Glaphyromorphus nigricaudus is a secretive species restricted to tropical northeast Queensland, Australia. Like most of its genus, it prefers shaded moist habitats and is reported to be nocturnal-crepuscular, but is sometimes active during the day (Cogger 2000. Reptiles and Amphibians of Australia, Reed Publishing, Sydney, Australia. 808 pp.). While conducting fieldwork at Trinity Beach in northeastern Australia (145.6978°E, 16.7861°S; datum: AGD66; elev. 0.9 m) at 1453 h EST on the 17 February 2001, I observed an adult *G. nigricaudus* patrolling 5–10 cm from a well-established Green Ant (*Oecotsylla smaragolia*) column oriented in an eastward direction. Many of the ants were transporting prey back to a nest located in a nearby tree. Over a period of 18 min, I observed the lizard lunge quickly at individual ants carrying specific prey. Following each successful lunge, the lizard would retreat a short distance from the column (20–40 cm) to consume the prey. From a nearby vantage point, I determined that the majority of prey items targeted by the lizard were lepidopteran larvae.

The cryptic nature and high diversity of Australian skinks (Cogger, *op. cit.*) implies that the frequency with which prey piracy occurs among Australian skinks may be substantially underestimated. Nonetheless, at least four other cases of skink species opportunistically stealing prey (directly or indirectly) from other predators have been reported. Three of these records involve cases of direct piracy from ant columns by the diurnal species *Carlia munda* (Bedford 1995. Herpetol. Rev. 26:99–100.), *Cryptoblepharus virgatus* (Greer 1989. The Biology

and Evolution of Australian Lizards. Surrey Beatty and Sons, Chipping Norton, Sydney. 264 pp.) and *Morethia boulengeri* (as *Ablepharus lineoocelatus*) (Chisholm 1923. Aust. Zool. 3:60–71). A fourth observation was the theft of arthropod prey from eumenid mud-wasp nests involving *Cryptoblepharus virgatus* (Phillips 2005. Herpetofauna 35:120). Members of the genus *Glaphyromorphus* are almost entirely terrestrial, crepuscular, and secretive in habit (Greer, *op. cit.*), suggesting that high energy prey, such as lepidopteran larvae, might be available only infrequently. If this is the case, instances of prey piracy, as I report here, might provide such species with an additional and energetically favorable form of prey.

Submitted by **BRETT A. GOODMAN**, James Cook University, Townsville 4811, Queensland, Australia; e-mail: brett.goodman@jcu.edu.au.

LEPIDOBLEPHARIS XANTHOSTIGMA (NCN). **ENDOPARASITES.** *Lepidopblepharis xanthostigma* is a small gecko that inhabits leaf litter and occurs from southeastern Nicaragua and northwestern Costa Rica to northern Colombia (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). To our knowledge, only one report of an endoparasite from this species exists; Goldberg and Bursey (2004. Herpetol. Rev. 35:268) reported acanthocephalan (Oligacanthorhynchidae) cystacanths from this host. The purpose of this note is to add the nematode *Porrocaecum* sp. to the list of endoparasites of *L. xanthostigma.*

The coelomic cavity of one mature female *L. xanthostigma* (28 mm SVL) from the herpetology collection of the Natural History Museum of Los Angeles County (LACM 114228) collected in Puntarenas Province, Costa Rica (8.7167°N, 83.4667°W; datum: WGS84; elev. 38 m) in May 1971 was examined for helminths. The body cavity was opened and the visceral organs were examined under a dissecting microscope. Two larvae were found in cysts in the liver. They were cleared in a drop of undiluted glycerol on a glass slide, examined with a compound microscope and assigned to the genus *Porrocaecum.* The larvae were deposited in the United States National Parasite Collection, Beltsville, Maryland as (USNPC 100467).

Adults of *Porrocaecum* live in the intestines of birds; eggs pass with the feces and are eaten by earthworms in which they hatch (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission, 2nd ed. CABI Publishing, Oxfordshire, UK, 650 pp.). Vermivorous verebrates may act as paratenic (= transport) hosts; larvae mature when ingested by an appropriate host (Anderson, *op. cit.*). *Lepidoblepharis xanthostigma* represents a new paratenic host record for *Porrocaecum* sp. and can be added to the list of poikilothermic Costa Rican vertebrates serving as transport hosts: *Amastridium veliferum, Chironius carinatus, Dendrophidion pericarinatus, Dendrophidion vinitor, Erytholamprus bizonus, Liophis epinephelus, Oxybelis brevirostris, Micrurus nigrocinctus* (Goldberg and Bursey 2004. Carib. J. Sci. 40:62–69); *Coniophanes fissidens, Rhadinaea decorata, Plicocercus euryzonus* (Goldberg and Bursey 2007. Phyllomedusa 6:69–72); *Lithobates taylori, Lithobates vaillanti* (Goldberg and Bursey 2007. Carib. J. Sci. 43:65–72); and *Lithobates warszewitschii* (Bursey and Goldberg 2007. Carib. J. Sci. 43:1–10).

We thank Christine Thacker (LACM) for permission to examine the *L. xanthostigma* that is part of the CRE collection donated in 1998 by Jay Savage.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 909608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

LIOLAEMUS CUYANUS (NCN). **CLUTCH SIZE.** *Liolaemus cuyanus*, a medium-sized sand lizard belonging to the "*darwinii*" complex (Abdala 2007. Zootaxa 1538:1–84), has a wide distribution, living in dunes in Neuquén, La Pampa, Mendoza, San Juan, La Rioja, and Catamarca provinces. This species occurs in habitats dominated by xerophyllous vegetation (primarily *Larrea divaricata*, *Bulnesia retama*, and *Opuntia*, *Trichocereus*, and *Echinopsis* cacti species). Other than a description of it being oviparous (Cei 1986. Reptiles del Centro, Centro-oeste y Sur de la Argentina. Herpetofauna de Zonas Áridas y Semiáridas. Monografie IV. Museo Regionale di Scienze Naturali Torino, Italy. 527 pp.), few data exist regarding its reproductive biology (Blanco et al. 2002. XVI Reunión de Comunicaciones Herpetológicas. La Plata, Argentina. 32 pp.). Hence, we report the first data on clutch size in *L. cuyanus*.

On 4 November 2007, we captured a gravid female (71 mm SVL) *L. cuyanus* at Los Baldecitos, Valle Fértil Department, San Juan Province (30.22°S, 67.68°W; datum: WGS84; elev. 1239 m) in the shade of a *Larrea cuneifolia* shrub on reddish sandy that matched its dorsal coloration. We placed this female in a 120 cm × 60 cm × 40 cm terrarium with abundant sand and gravel, and provided larval beetles and water *ad libitum*. On 2 December 2007, the female laid 7 eggs. We measured the length and width of each egg with Vernier calipers to the nearest 0.1 mm. The volume of each egg was calculated using the formula of an ellipsoid sphere (Dunham 1983. *In* Huey et al. [eds.], Lizard Ecology, pp. 261–280. Harvard University Press, Cambridge, Massachusetts). Eggs averaged 14.2 mm (s = 1.1) long; 8.3 mm (s = 0.2) wide; and 292.4 mm^3 (s = 31.4) in volume. This clutch size may approximate what is typical for this species. *L. cuyanus* females from Médanos Grandes (Caucete Department), located 178 km SW of the Baldecitos population were reported to have a mean clutch size of 7.9 (Blanco et al., *op. cit.*). These authors mentioned that *L. cuyanus* displays follicular activity over a lengthy season (September–March) and commonly lays two clutches annually.

We deposited the eggs in the herpetological collection of the Instituto y Museo de Ciencias Naturales, Universidad Nacional de San Juan. We thank Y. Heredia and V. Pesce for help in the field and G. Blanco for generously providing reproductive data on *L. cuyanus*.

Naturales, Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan, Avenida España 400(n), Caixa Postal 5400, San Juan, Argentina.

LIOLAEMUS INACAYALI (NCN). **MAXIMUM SIZE.** *Liolaemus inacayali*, a recently described species, inhabits Provincia de Rio Negro, Argentina (Abdala 2003. Cuad. Herpetol. 17:3–32). Available size data from the species description indicate that 10 individuals measured ranged from 57.3 to 75.3 mm SVL (mean = 63.7 mm). Here, we report on an additional *L. inacayali* that considerably exceeds the known maximum size.

In the Juan Carlos Acosta (JCA) herpetological collection, we discovered an adult male *L. inacayali* (no number collection) collected by Graciela Blanco in December 1991 in Ingeniero Jacobacci, Departamento 25 de Mayo, Provincia de Río Negro (41.28°S, 69.57°W; elev. 894 m) with a SVL of 77.3 mm. This individual, like others of its species, was collected from a very arid habitat with high daily and seasonal temperature variation and low annual precipitation (< 200 mm.), principally as snow. The soil is composed of sand derived from interspersed volcanic and sedimentary rocks. Vegetation consists of low spiny shrubs typical of central Patagonia.

The specimen is deposited in the Universidad Nacional de San Juan herpetological collection (IMCN-UNSJ-3015).

Submitted by **ALEJANDRO LASPIUR (**e-mail: laspiursaurus@gmail.com) and **JUAN CARLOS ACOSTA,** Departamento de Biología, Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan. Avenida España 400 (N), Caixa Postal 5400, San Juan, Argentina.

SCELOPORUS OCCIDENTALIS (Western Fence Lizard). **PREDATION**. Invertebrate predators such as spiders, scorpions, and mantids occasionally feed on immature lizards (Jehle et al. 1996. Herpetozoa 9:157–160; Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. University of California Press, Berkeley, California. 333 pp.; Prete et al. [eds.] 1999. The Praying Mantids. Johns Hopkins University Press, Baltimore, Maryland. 400 pp.). However, documentation of such events is sparse. Here, I report an observation of predation on *Sceloporus occidentalis* by the European mantid, *Mantis religiosa*, an introduced species previously reported to prey on lizards in Europe (Jehle et al., *op. cit.*), and that is now widespread in the United States.

At 1220 h on 2 September 2006 (air temperature 25.3ºC), I observed a female *M. religiosa* (73 mm body length) feeding on a hatchling *S. occidentalis* (ca. 32–35 mm SVL, Fig. 1) 24.6 km SW of Idaho City, Boise Co., Idaho, (43.6367°N, 115.9975°W, datum: WGS84; elev. 995 m). When discovered, the mantid momentarily stopped feeding, but it had already consumed the head, neck, left foreleg, and some of the upper left trunk region of the lizard. Without further disturbance, the mantid resumed feeding another 15–20 min, and photographs were taken during this time. After feeding, the mantid left the carcass remnant and climbed into adjacent *Rudbeckia* flowers. The mantid was not collected, but was identified as *M. religiosa* by the occurrence of a large black-ringed spot on the anteroventral surface of the forecoxa, near the base (Helfer 1987. How to Know the Grasshoppers, Crickets, Cockroaches and their Allies. Dover Publications, New York, New York. 363 pp.).

FIG. 1. *Mantis religiosa* feeding on *Sceloporus occidentalis*, Boise Co., Idaho, 2 September 2006.

I made the observation in a ca. 60 ha unincorporated residential subdivision located in the foothill shrublands-grasslands ecoregion of Boise County (McGrath et al. 2002. Ecoregions of Idaho. USGS. Reston Virginia. U.S. Geological Survey map, scale 1:1,350,000) and surrounded by thousands of hectares of similar habitat. *Sceloporus occidentalis* have been observed in this subdivision for more than 25 years (pers. obs.). However, *M. religiosa* was likely introduced to the subdivision less than 15 years ago (DRB, unpubl. data) and has since become abundant; on 6 August 2007, I observed 14 mantids in ca. 66 m^2 of unmowed largely graminoid vegetation 106 m ENE from the aforementioned site of observation. Areas with high densities of generalist invertebrate predators, such as *M. religiosa*, may increase the likelihood of small vertebrates becoming prey.

I thank Jack W. Sites, Jr. (Brigham Young University) for identifying the lizard. It was deposited in the BYU herpetological collection (BYU 4426). William H. Clark (Orma J. Smith Museum of Natural History, College of Idaho, Caldwell) provided helpful suggestions on this note.

Submitted by **DONALD R. BROTHERS**, 80 Kirk Drive, Boise, Idaho 83716, USA; e-mail: probes@q.com.

TROPIDURUS ITAMBERE (Rock Lizard). **SOCIAL INTERACTIONS.** Visual signals are used in many different social contexts, incluing territory advertisement, courtship, and intrasexual interactions (Bradbury and Vehrencamp 1998. Principles of Animal Communication. Sinauer Associates, Sunderland, Massachusetts. 882 pp.). Nearly all lizard species display some form of intraspecific aggression ranging from specific site defense (e.g., basking sites or burrows) to home range defense (Stamps 1977a. *In* Gans and Tinkle [eds.], Biology of the Reptilia: Volume 7. Social Behavior and Spacing Patterns in Lizards, pp. 265–334. Academic Press, New York). Herein, we provide the first description of courtship and territorial behavior for the saxicolous lizard *Tropidurus itambere*. This is a medium-sized lizard (mean adult SVL = 71.8 mm) that commonly occurs in open, sometimes rocky, areas in central and southeastern Brazil (Rodrigues 1987. Arq. Zool. São Paulo 31:105–230). Females

have a seasonally distinct reproductive cycle from the end of the dry season to the end of the rainy season (October–March), whereas some males are reproductive year-round (Van Sluys 1993. J. Herpetol. 27:28–32).

We made field observations in August and December 2007 (end of the dry season and rainy season, respectively) in a rocky open area at Parque Estadual do Ibitipoca, state of Minas Gerais, southeastern Brazil (21.67°–21.73°S and 43.87°–43.92°W; elev. 1200 m). We first observed courtship behavior (Fig. 1) at 1330 h on 13 August on a rock substrate. An adult female (73.8 mm SVL) was on the rock raised up on four legs, arching her back with her tail raised when a large male (84.4 mm SVL) approached her and bit her neck just once (Fig. 1A). The female moved away from male while he remained in place and both lizards then inflated their gular regions while head bobbing. The female arched her back and again presented her raised tail to the male (Fig. 1B) while he continued to perform head bobs with the gular region inflated. The lizards remained this way for ca. 20 sec, then the male approached the female and pushed her cloacal region, sometimes successively, with his nose (Fig. 1C). Subsequently, the two lizards arched their backs and inflated their gular regions while the female remained with her tail raised. The male then rushed the female once more, attempting to bite her neck twice, and the female again moved away. We did not observe copulation.

At 1500 h on 16 August, we observed an aggressive interaction between two males. For a few seconds, a larger male (86.9 mm SVL) was on a rock with the gular region inflated and head bobbing with the forelimbs extended toward a smaller male (75.8 mm SVL). The larger male then jumped off rock and chased the smaller male, who fled to nearby vegetation. A few minutes later, the larger male was observed copulating with a smaller female (67.8 mm SVL) near to where the smaller male had been chased.

At 1000 h on 1 December, we observed a similar agonistic interaction, but between two females. The larger female (76.8 mm SVL) was on a rock when a smaller female (63.6 mm SVL) approached her. Soon after, the larger female arched her back and began to head bobbing with the forelegs extended. She then jumped off the rock and approached the other female with the gular region inflated while head bobbing and chased smaller female, who fled to nearby vegetation. Subsequently, the aggressive female returned to the same rock.

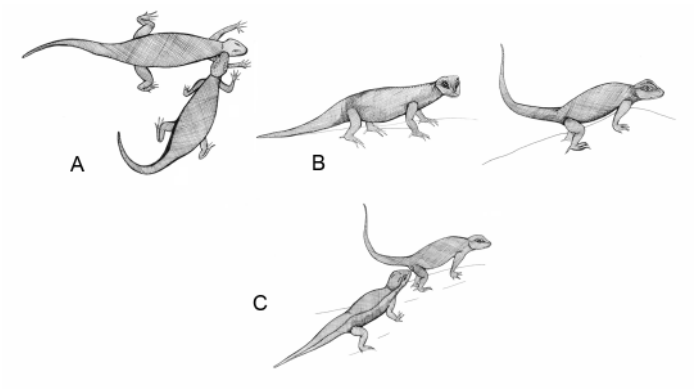

FIG. 1. Courtship behavior of *Tropidurus itambere* observed in a rocky open area situated at Parque Estadual do Ibitipoca, in Minas Gerais, southeastern Brazil.

Courtship behavior we describe for *T. itambere* was similar to that reported for others *Tropidurus* (Àvila and Cunha-Avellar 2006. Herpetol. Rev. 37:473; Carpenter 1977. Herpetologica 33:285–289). Tail raising has been attributed to play a role in courtship interactions and female rejection behavior (Carpenter 1977. Herpetologica 33:285–289; Martins 1991. Anim. Behav. 41:403–416; Martins 1993. Anim. Behav. 45:25–36). According to Stamps (1977a., *op. cit.*) and Fitch (1981. Misc. Publ. Mus. Nat. Hist. Univ Kansas 70:l–72) males and females in the Tropiduridae generally show home-range defense or are territorial. Van Sluys (1997. Copeia 1997:623–628) found that the overlap between home ranges within sexes in *T. itambere* is low and suggested that both sexes are territorial, but no descriptions of aggressive behaviors were provided. Our observations revealed that male and female *T. itambere* display aggressive behaviors when defending their areas, as has been observed for *T. albemarlensis* (Stebbins et al. 1967. Ecology 48:839–851) and *T. delanonis* (Werner et al. 1978. Z. Tierpsychol. 47:337–395). Field studies performed by Stamps (1977b. Ecology 58:349:358) using the lizard *Ano1is aeneus* as a model may indicate that females compete for food and males for mates.

We thank the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for the financial support, Ana Elisa Resgalla do Nascimento for suggestions on the manuscript and Sthefane D'ávila de Oliveira e Paula for the illustration.

SQUAMATA — SNAKES

ATRACTUS TORQUATUS (Rusty Earth Snake). **DIET**. Based on reports available in the literature, this Amazonian snake preys primarily on earthworms; however mites, beetles, and flies have also been reported as prey (Martins and Oliveira 1993. Zool. Meded. 67:21–40). Here we report the first evidence of this species feeding on a vertebrate. On 20 November 2002, at 1414 h, we collected an adult male *Atractus torquatus* (INPA-H 10932; 472 mm total length, 28.29 g) at Reserve Adolpho Ducke, in the municipality of Manaus, Amazonas state, Brazil (2.950°S, 59.917°W, WGS 84, 60 m elev.). We found a single amphibian—the caecilian *Rhinatrema bivittatum* (INPA-H 16057; 238 mm total length; 8.3 g)—in the digestive tract. This observation gives evidence that *A. torquatus* is capable of feeding on caecilians and possibly other limbless, fossorial vertebrates and invertebrates of comparable sizes. Additional evidence of the ability to consume large, limbless prey is a report of an *A. torquatus* preying on a giant earthworm (180 mm total length; Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150).

BOTHROCOPHIAS HYOPRORA (Amazonian Hog-nosed Pit Viper). **DIET**. *Bothrocophias hyoprora* is a forest-dwelling terrestrial snake with a diet that includes centipedes, frogs, lizards, marsupials, and rodents (see Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publishing, Eagle Mountain, Utah; Cisneros-Heredia et al. 2006. Herpetozoa 19:17–26). There are few specific reports of this species' diet in the literature. On 11 March 2003 at 0700 h a juvenile *B. hyoprora* (298 mm SVL, 15 g after prey removal) was captured in a forest at Reserva Biológica do Jaru (10.1447222°S, 61.9075°W), Ji-Paraná, Rondônia, Brazil. Upon dissection, we discovered a frog *Allobates femoralis* (Aromobatidae; 32 mm SVL, 2.3 g) in the snake's stomach that had been ingested head-first. This is the first report of *A. femoralis* in the diet of *B. hyoprora*. The snake was deposited in the herpetological collection of Universidade Federal do Acre, Campus Floresta (UFACF 216) in Cruzeiro do Sul, State of Acre, Brazil.

Submitted by **PAULO SÉRGIO BERNARDE**, Universidade Federal do Acre – UFAC, Campus Floresta, Centro de Ciências Biológicas e da Natureza, Cruzeiro do Sul, AC, 69980-000, Brazil (e-mail: SnakeBernarde@hotmail.com); **LUIZ SÉRGIO FERREIRA MARTINS** (e-mail: sfmluiz@gmail.com), and **JULIANO RODRIGUES OLIVEIRA**, Reserva Biológica do Jaru – IBAMA, Rua São Cristóvão 903, Bairro Jardim Presidencial III, Ji-Paraná, RO, 78962-590, Brazil (e-mail: juliano.oliveira@ibama.gov.br).

BOTHROPS ATROX (Amazonian Lancehead). **DIET**. *Bothrops atrox* is a euryphagous pitviper that feeds on centipedes, fishes, frogs, lizards, snakes, birds, and small mammals (see Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publishing, Eagle Mountain, Utah and citations therein; Oliveira and Martins 2003. Herpetol. Rev. 34:61–62; Macedo-Bernarde and Bernarde 2005. Herpetol. Rev. 36:456). On 16 March 2006 at 2030 h we captured an adult *B. atrox* (620 mm SVL, 334 g after prey removal) in a pasture near Parecis (12.18°S, 61.60°W), Rondônia, Brazil. Upon dissection, we found a *Taraba major* (Aves: Passeriformes: Thamnophilidae; 88 g) in the snake's stomach that had been ingested head-first. Birds are infrequent in the diet of this pitviper (Martins and Gordo 1993. Herpetol. Rev. 24:151–152; Martins et al. 2002, *op. cit.*). This is the first report of *T. major* in the diet of *B. atrox*. The snake was deposited in the herpetological collection of Universidade Federal do Acre, Campus Floresta (UFACF 215) in Cruzeiro do Sul, State of Acre, Brazil.

Submitted by **PABLO FACHIN NASCIMENTO**, Faculdade de Ciências Biomédicas de Cacoal - FACIMED, Avenida Cuiabá nº 3.087, Jardim Clodoaldo, Cacoal, RO, 78976-005, Brazil (e-mail: pablo_bio21@hotmail.com); **PAULO SÉRGIO BERNARDE**, Universidade Federal do Acre – UFAC, Campus Floresta, Centro de Ciências Biológicas e da Natureza, Cruzeiro do Sul, AC, 69980-000, Brazil (e-mail: SnakeBernarde@hotmail.com); and **DANTE RENATO CORRÊA BUZZETTI**, Centro de Estudos Ornitológicos, Rua Álvaro Rodrigues 163 sala 4, São Paulo, SP, 04582-000, Brazil (e-mail: dante@dantebuzzetti.com.br).

CROTALUS RAVUS (Mexican Pygmy Rattlesnake). **DIET.** *Crotalus ravus* is a small rattlesnake restricted to the temperate montane regions of the Mexican Plateau southward to the Mesa del Sur in Oaxaca and the Sierra Madre del Sur in Guerrero (Campbell and Lamar 2004. Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 870 pp.). *Crotalus ravus* has been documented to consume a variety of vertebrate and invertebrate prey, including crickets, anurans, lizards, and rodents (Campbell and Armstrong 1979. Herpetologica 35:304–317; Sánchez-Herrera 1980. Bull. Maryland Herpetol. Soc. 16:9–18; Mendoza-Hernández et al. 2004. Herpetol. Rev. 35:63–64). Here we document the consumption of a snake by *C. ravus*.

On 21 July 2002 we collected a juvenile *C. ravus* in pine-oak forest near Colonia Zacamulpa, Municipality of Huixquilucan, Estado de México, Mexico (19.4141667°N, 99.3055556°W, elev. 2750 m). This snake was deposited in the herpetological collection of Instituto Tecnológico de Huejutla (ITAH 1412). Upon dissection, we found that the snake (SVL 308 mm, mass 19.8 g) had ingested a medium-sized colubrid snake, *Storeria storerioides* (ITAH 1412b; SVL 225 mm, tail length 60 mm, mass 10.7 g), head-first (Fig. 1). The approximate prey/predator mass ratio was 0.54. This is the first report of ophiophagy in *C. ravus*, and extends our knowledge about the diet of this rattlesnake.

We thank Jonathan Campbell for reviewing the manuscript. Research and collecting were conducted under the authority of SEMARNAT scientific research permits OFICIO NÚM/SGPA/DGVS/02100 issued to FMQ and RWB.

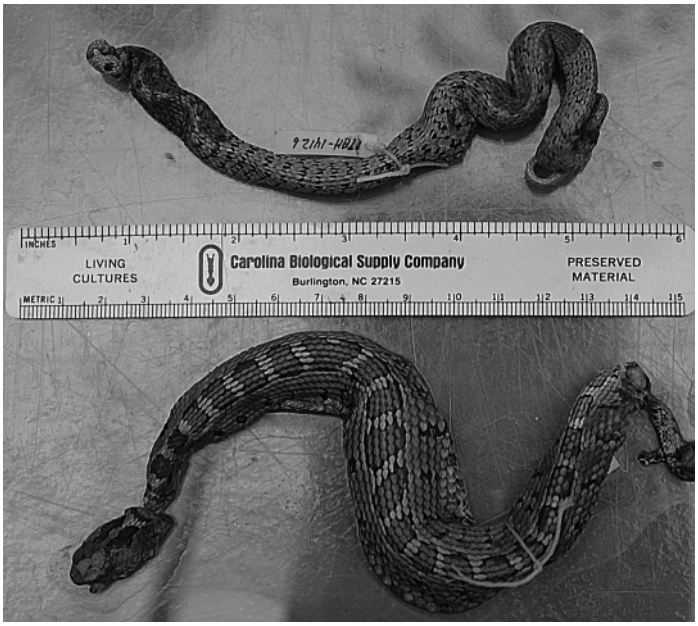

FIG. 1. A juvenile *Crotalus ravus* and prey (*Storeria storerioides*); approximate prey/predator mass ratio 0.54.

HETERODON NASICUS (Western Hog-nosed Snake). **PREDATION.** Although predation on *H. nasicus* by avian predators has been reported in the literature (Ernst and Ernst. 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.) few instances have been documented, and we know of no accounts of predation on *H. nasicus* by Loggerhead Shrikes (*Lanius ludoviscianus*). Loggerhead shrikes are known to prey on a wide array of vertebrates including reptiles (Lefranc 1997. Shrikes. A Guide to the Shrikes of the World. Yale University Press, New Haven and London. 192 pp.). On 23 May 2005 we found a small male *H. nasicus* (171 mm SVL, 33 mm tail, 4.8 g) that was dead and draped over a branch at ground level under a soapberry tree (*Sapindus saponaria*) at the Caprock Wildlife Area, Chaves County, New Mexico, USA (33.4418653°N, 103.8165683°W, NAD 83). The snake had a 7 mm long by 3 mm wide wound on the right side of the body, between 43 and 50 mm from the snout near the snake's heart. We presumed predation by a Loggerhead Shrike due to the nature of the wounds, the position of the snake on the branch, and the presence of shrikes in the immediate area for weeks before and after the incident described above. The specimen was deposited at the Texas Cooperative Wildlife Collection, Texas A&M University (TCWC 89794).

LAMPROPELTIS CALLIGASTER (Prairie Kingsnake). **ACTIVITY**. At high elevations snakes are known to emerge from winter hibernacula to bask on warm winter days (Hansknecht et al. 1999. Herpetol. Rev. 30:104), but information on snake activity away from hibernacula during cold temperatures is rare or lacking. On 27 December 2006, I encountered a recently killed female *Lampropeltis calligaster* (864 mm SVL, 101 mm tail) on the center dividing line of East Clarksville Road (Clark County Road 8), ca. 3 km NW of Marshall, Illinois, USA (39.4136111°N, 87.7275°W, WGS84; 180 m elev.). The cause of death was obviously by automobile, but the snake appeared in good physical condition otherwise. The temperature at the time of this encounter was ca. 1°C. It is possible that the snake was hibernating on a bank adjacent to or underneath the road, emerging to bask on the road. Because the snake was in the center of the road, however, it is likely that the snake was actively crossing the road. Furthermore, although December 2006 was warmer than typical Decembers (2006 mean high and low temperatures = 7.00°C and –1.94°C, respectively; normal mean high and low temperatures = 3.89°C and –4.61°C, respectively), days immediately prior to and the day of this encounter were not particularly warm. The mean high and low temperatures for the three days prior to encountering the animal were 4.07°C (± 0.19) and –0.56°C (± 0.64**)**, respectively. On 27 December 2006, the high and low temperatures were 2.22°C and –2.22°C, respectively.

I thank J. Angel for providing climatological data from a local weather station.

LICHANURA ORCUTTI (Rosy Boa). **PREDATION**. The most common natural source of mortality for snakes is predation by various vertebrates (Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.). In arid western North America, some bird species in particular are known to prey heavily on snakes (e.g., Roadrunners, *Geococcyx californicus*; Red-tailed Hawks, *Buteo jamaicensis*, Golden Eagle, *Aquila chrysaetos*; Terres 1991. The Audubon Society Encyclopedia of North American Birds. Wing Books, New York, New York. 1109 pp.; Steenhof and Kochert 1988. J. Anim. Ecol. 57:37–48). We report here evidence of raptor predation on *Lichanura orcutti* (= *Lichanura trivirgata roseofusca*, Coastal Rosy Boa; see Wood et al. 2008. Mol. Phylogenet. Evol. 46:484–502) in southern California.

On 7 May 1999, an adult male *L. orcutti* implanted with a transmitter was radiotracked at the Santa Margarita Ecological Reserve, Riverside County, as part of an ongoing telemetry study in southern California (Diffendorfer et al. 2005. J. Herpetol. 39:24–36). On day five of the tracking effort for this snake, we recovered the skeletal remains (along with transmitter) from a raptor nest ca. 400 m upstream from the last point of capture. Ten additional *L. orcutti* were radiotracked along San Pasqual Valley, San Diego County, California. On 07 February 2000 (after 214 days of monitoring), an adult male implanted with a transmitter was found dead (with transmitter intact) within an agricultural field ca. 300 m from the last point of capture. The snake bore several puncture wounds across the length of the body. The distance moved by this individual greatly exceeded distances traveled per move for individuals (N = 10) of this population (distance per move ranged from 15.8–63.2 m; Diffendorfer et al., *op. cit.*). We presume this incidence represents an attempted predation event by a raptor, but was subsequently dropped while in flight and never recovered.

Although we were not able to determine the species of raptor for either observation, Red-tailed Hawks (*Buteo jamaicensis*) and Golden Eagles (*Aquila chrysaetos*) occur at both of these study sites, although Red-tailed Hawks were observed more frequently. To our knowledge, these are the first reports of predation on *Lichanura* by raptors, although we cannot rule out the possibility

of scavenging by raptors given that the act of predation was not observed.

Submitted by **DUSTIN A. WOOD, CARLTON J. ROCHESTER,** and **ROBERT N. FISHER,** U.S. Geological Survey, Western Ecological Research Center, San Diego Field Station, 4165 Spruance Road, Suite 200, San Diego, California 92101, USA.

MORELIA SPILOTA SPILOTA (Diamond Python). **REPRODUCTION**. *Morelia spilota spilota* is a medium-sized (up to 3 m and 6 kg) boid inhabiting rocky outcrops, scrub, woodland, and disturbed urban areas of coastal southeastern Australia (Shine and Fitzgerald 1996. Biol. Cons. 76:113–122; Slip and Shine 1988a. Aust. Wildl. Res. 15:515–531). Sexual maturity is reached at 150 cm snout–vent length with breeding occurring in spring (late September to early November). Breeding aggregations of one female and several males are often formed which can last several months (Slip and Shine 1988b. Herpetologica 44:396–404). Here we report an unusual reproductive event involving a captive female *M. s. spilota* and wild male *M. s. spilota* that occurred prior to the recognized breeding season.

On 23 August 2007, a wild male *M. s. spilota* (1460 mm SVL; 1691 mm TL; 1.30 kg) entered a house in Berry (34.7652778°S, 150.6780556°E), NSW, Australia, through an open window at night. The male was discovered on the wire mesh screen top of a glass tank attempting to access a captive-born virgin female *M. s. spilota* (1525 mm SVL; 1890 mm TL; 1.79 kg) housed inside. The male was captured and released the following day ca. 500 m away on a nearby nature reserve (34.7616667°S, 150.6811111°E). On 28 August 2007, the same male *M. s. spilota* (identifiable by a distinctive missing tail tip) was again discovered on top of the tank attempting to access the captive female. At this time, CHB removed the screen top, the male python entered the cage, the screen top was replaced, and the pair began copulating within minutes. The pythons remained entwined and appeared to copulate multiple times until 6 September 2007, although it was often difficult to ascertain intromission depending on how the snakes were situated. On 6 September, the male appeared to lose interest and was released.

For a number of snake species, it appears that pheromones are substrate-bound substances (Aldridge et al. 2005. Amphibia-Reptilia 26:576–582; Carmichael et al. 2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 227–240. Eagle Mountain Publishing, Eagle Mountain, Utah). This has also been suggested for *M. s. spilota*, with females depositing pheromone trails to attract males (Slip and Shine 1988b, *op. cit.*). However, this reproductive encounter between a captive female *M. s. spilota* and wild male *M. s. spilota* indicates that pheromones could perhaps be airborne in *M. s. spilota*. We do not discount the possibility that the male python entered the house following non-pheromonal cues as part of its normal activity range, or that the male used spatial mapping or some other form of orientation to return to the house after being relocated. However, we suspect that the male was following pheromonal cues when he gained his first entry because: a) the window through which the male entered had been closed for three months during the winter and the male entered within three days of the window being opened; and b) no pythons had been seen previously in the vicinity of the house during > 7 years of occupancy by CHB. We suggest that more controlled investigations of the volatility of boid pheromones could have potential management applications, such as pheromone traps for invasive *Python molurus* or *Boa constrictor* in south Florida, USA.

NERODIA CLARKII (Saltmarsh Watersnake). **PREDATION**. To our knowledge, there are no published observations of predation on *Nerodia clarkii*. Several authors have suggested that potential predators might include any large vertebrate or invertebrate such as fish, crabs, wading birds, snakes, alligators, or crocodiles (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 218 pp.); Gibbons and Dorcas 2004. North American Watersnakes. University of Oklahoma Press, Norman, Oklahoma. 438 pp.). *Nerodia clarkii* is the most salt tolerant member of its genus and presumably is exposed to more marine predators than its congeners. Of these predators, *Callinectes sapidus* (Blue Crab) represents a more formidable invertebrate predator than those that would be typically encountered by most species of *Nerodia*.

During a herpetological survey of the Gulf Islands National Seashore, Mississippi District, Mississippi, USA, we observed an apparent predation attempt on *N. c. clarkii* on West Ship Island (30.2091667°N, 88.9783333°W [NAD83]). On 30 March 2006 at 1226 h we captured a *N. c. clarkii* (404 mm SVL) in a small, isolated pool in a *Juncus* sp. saltmarsh. After processing, we released the snake onto the bank where it remained for about five minutes. The snake then entered the pool where it was quickly grasped both at mid-body and just posterior to the head by a large female *C. sapidus*. With the *N. c. clarkii* firmly secured, the crab moved toward the deeper middle section of the pool pulling the snake's head just below the water surface. Once the head was submerged, the crab remained motionless for approximately two minutes, while the *N. c. clarkia* fully extended its body, stretching toward the surface. While attempting to photo-document this event, we disturbed the crab, subsequently causing the release of the snake. However, it seemed unlikely that the snake would have escaped without this intervention. Although crabs have been hypothesized as a potential predator of *N. clarkii* (Gibbons and Dorcas 2004, *op. cit.*), this is the first published report of crab predation on *N. clarkii*.

OPHEODRYS AESTIVUS (Rough Green Snake). **PREDATION**. Known avian predators of *O. aestivus* include four species of hawks (*Buteo*), Cattle Egret (*Bubulcus ibis*), Loggerhead Shrike (*Ludius ludovicisnus*), Blue Jay (*Cyanocitta cristata*), Florida Scrub Jay (*Aphelocoma coerulescens*), American swallow-tailed kite (*Elanoides forficatus*), and two species of owls (*Otus, Steotyto*) (Hammerson. 1988. Herpetol. Rev. 19:85; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 668 pp. and references therein). We report here an observation of yet another avian predator of *O. aestivus*.

On 15 May 2007, we observed an Osprey (*Pandion haliaetus*) catch an adult *O. aestivus* while the snake was swimming on the surface of Chickahominy Lake, about 3–4 m north of the southern shoreline, New Kent County, Virginia (37.4095°N, 76.9395°W). The Osprey carried the snake to the top of a cypress tree where it apparently killed and partially ate it before dropping the snake and flying off. The snake fell out of the tree and died. The only obvious external injury was a lesion at the snake's midbody. *Opheodrys aestivus* has been observed swimming in fresh water (Raun 1965. A Guide to Texas Snakes. Texas Mem. Mus., Mus. Notes (9):1–85) making them easy targets for Ospreys that search for fish and other aquatic prey at or just below the surface. This is the first report of an Osprey as a predator of *O. aestivus*.

OXYBELIS AENEUS (Brown Vine Snake). **ENVENOMATION**. On 1 June 2004 at 1205 h, I encountered an *Oxybelis aeneus* (ca. 920 mm total length) swimming eastward in a freshwater canal ca. 80 m northeast from the port at Moin, Limón Province, Costa Rica. Diving attacks at a thread-like serpentine movement by a *Pitangus sulphuratus* (Great Kiskadee) initially alerted my group to the snake's presence. The boat was driven to shore within 1 m of the snake's exit from the water. I grabbed the snake mid-body and was bitten between my left thumb and index finger. The snake chewed vigorously for at least 1 min before I was able to gently release its mouth. After several photographs, it was released unharmed near its capture site. After 5 min, I experienced a slight to moderate burning sensation in the area of the bite. This subsided considerably after ca. 10 min. There was no evidence of swelling or excessive bleeding, but a slight dark discoloration began to appear at the site of the bite. After 20 min, my left thumb, left index finger, and the surrounding portion of my hand were completely numb but exhibited normal range of motion. Approximately 45 min later, feeling had returned to the entire left hand, but there was still slight pain at the point of envenomation. The pain was completely gone by the following morning. The discoloration at the area of the bite faded gradually and was completely gone by 6 July 2004. No further complications were experienced.

I thank C. Fielitz, C. Puttock, A. Riley, W. T. Heath, and C. C. Green for assistance.

OXYRHOPUS RHOMBIFER BACHMANNI (False Coral Snake). **PREDATION/SCAVENGING**. On 7 March 2004, HMC found an apparently road-killed Geoffroy's Cat (*Oncyfelis geoffroyi*) with remains of a snake in its stomach. Based on coloration, pattern, and body shape, we identified the snake as *Oxyrhopus rhombifer bachmanni*, a medium-sized colubrid. The snake was too digested to determine sex, but we estimate its size to be at least 480 mm SVL. The cat was found on Ruta Nacional 3, 9 km S of junction Ruta Provincial 60, Biedma Department, Chubut Province, Argentina. The cat remains were discarded but the snake is deposited in Museo de La Plata herpetological collection (MLP.S 2597). We are unaware of any published accounts of predation on *O. r. bachmanni* by Geoffroy's Cat. An interesting issue is the fact that *O. r. bachmanni* is not reported for northern Chubut Province (Cei 1986. Museo Regionale di Scienze Naturali Torino, Monographie 4:1–527). The nearest reported locality is in northern Rio Negro Province, ca. 450 airline km distant. Thus, our observation may constitute a new locality for *O. r. bachmanni*, which is infrequently encountered even within its known distribution. Alternately, this is a case of introduction by human activities (e.g., in a cargo truck), as has been reported previously in another region of Argentina (Gomez and Acosta 1998. Multequina 7:73–75). We cannot be sure if the snake was dead or alive before the cat ate it, but its body was nearly flat, suggesting that the cat scavenged the snake from the roadway.

Submitted by **H. MARCELO CARRERA** and **LUCIANO J. AVILA** (e-mail: avila@cenpat.edu.ar), CENPAT-CONICET, Boulevard Almirante Brown s/n, U9120ACV, Puerto Madryn, Chubut, Argentina.

PANTHEROPHIS GLOYDI (Eastern Foxsnake). **BEHAVIOR.** *Pantherophis gloydi* is a large constrictor found only in parts of Ontario, Michigan, and Ohio (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians. Houghton Mifflin, New York. 616 pp.), with adults usually growing larger than 910 mm TL (Wright and Wright 1957. Handbook of Snakes of the United States and Canada. Comstock Publishing Associates, Ithaca, New York. 564 pp.). Much of what we know about this species' life history has been learned from radiotelemetry studies of adults (e.g. Willson and Brooks 2006. J. Herpetol. 40:285–289; MacKinnon et al. 2005. Can. J. Zool. 84:9–19). Because hatchlings and juveniles are seldom encountered in the wild (C. MacKinnon, A. Lawson, and R. Willson, pers. comm.), and because their small size precludes radiotransmitter implantation, relatively little is known about the life history of these younger age classes. Here, we report an elevated frequency of observation of young *P. gloydi*

on roads in the early fall in southern Ontario, Canada.

Data from 72 hatchling *P. gloydi* (≥ 3 clutches) indicate that the length of Pelee Island hatchlings ranges from 210 to 305 mm SVL (mean = 265.1 ± 21.8 mm [SD], N = 72, mean TL = 314.4 mm, range 252–367 mm; R. Willson, pers. comm.). Other reported *P. gloydi* hatchling lengths range from 254 to 356 mm TL (Wright and Wright 1957. *op. cit.*). Although little is known regarding the size at which *P. gloydi* attains sexual maturity, the shortest *P. gloydi* observed courting, mating, or gravid in the wild (Georgian Bay) measured 928 mm SVL for females (N = 58) and 1000 mm SVL for males (N = 54; A. Lawson, pers. comm.). Based on these data, we refer to snakes < 370 mm TL as young-of-year (YOY), snakes between 370 and 980 mm TL as juveniles, and to snakes ≥ 980 mm TL as adults (the presumed minimum adult total length assumes they have a tail length of at least 52 mm).

During a bicycle survey of wildlife on roads (118 trips total) conducted between 7 May and 26 October 2005 in both Point Pelee National Park and Rondeau Provincial Park, Ontario, we recorded 23 *P. gloydi* on roads (N = 14 Point Pelee; N = 9 Rondeau). Sixteen of these snakes (N = 10 Point Pelee; N = 6 Rondeau) were found between 28 September and 21 October, and all were YOY and juveniles (250–440 mm TL; Fig. 1). Seven larger snakes were observed prior to 10 August, with one snake eluding capture and measurement, three snakes measuring 650, 890 and 910 mm TL, and three adults exceeding 990 mm TL (Fig. 1). Although some of these large snakes were shorter than our 980 mm TL adult cutoff length, we believe that all were mature adults, given that their observed coloration was consistent with the pool of adults, rather than with the paler YOY and juveniles. In addition to our own observations, park staff and visitors at Point Pelee reported 10 *P. gloydi* on the road, including 6 small snakes (≤ 390 mm TL) found between 3 October and 17 October and four larger snakes found prior to 24 September (Figure 1; one adult unmeasured).

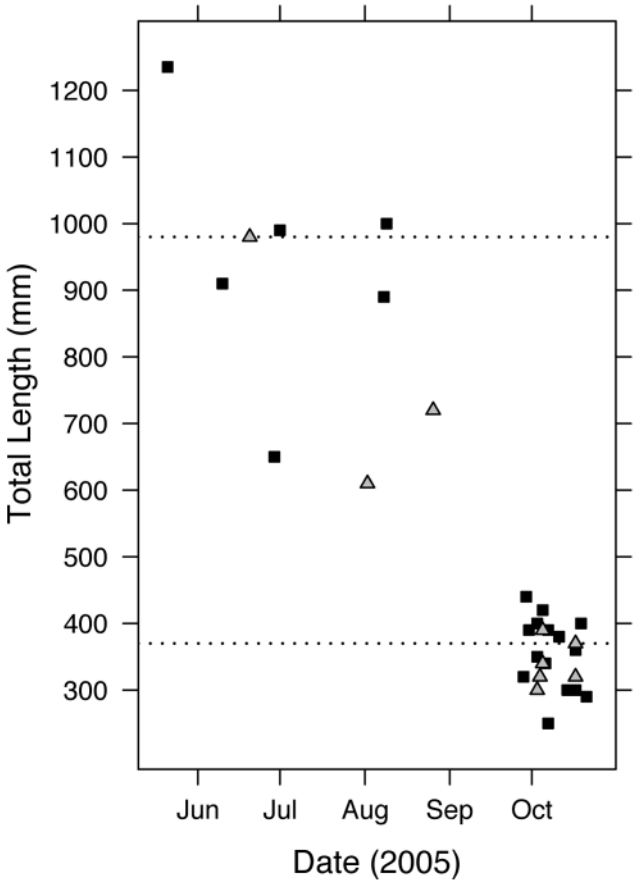

FIG. 1. Total lengths of *Pantherophis gloydi* encountered on Point Pelee National Park and Rondeau Provincial Park area roads between 7 May and 26 October, 2005. Black boxes correspond to sightings by the principal investigators and assistants; gray triangles correspond to anecdotal reports from park visitors and staff. Dotted lines define the narrowest (most conservative) estimated boundaries for the total length of juveniles of this species.

Pooling our observations and the anecdotal observations, we observed a cluster of exclusively small snakes within a period roughly coincident with expected hatching times (mid-August to October; Wright and Wright, *op. cit.*). Nine of the 16 small (≤ 440 mm) snakes formally observed during this time had lengths consistent with a YOY age class (< 370 mm). Our concurrent encounters with the remaining 7 slightly larger, but still sub-adult snakes could indicate that rapid post-hatching growth occurs among neonates in the wild, or alternatively that there is an increase in activity by juvenile age classes at the same time as neonate hatching and movement. We recommend that more intensive surveys be conducted during the late summer and early fall to explore whether increased encounters with juvenile age classes are the result of a seasonal dispersal event.

Submitted by **ROBERT G. FARMER** and **RONALD J. BROOKS**, Department of Integrative Biology, University of Guelph, 50 Stone Road East, Guelph, Ontario, N1G 2W1 (e-mail: farmerb@dal.ca).

PITUOPHIS RUTHVENI (Louisiana Pinesnake). **REPRODUCTION.** There are almost no data available on reproduction in wild *Pituophis ruthveni* (Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. University of Texas Press, Austin, Texas. 437 pp.).

On 4 July 2003 I observed an adult *P. ruthveni* in the possession of a private collector. The collector had captured the snake mid-day on approximately 22 June 2003 crossing a sand road in Bienville Parish near Sparta, Louisiana, USA. The snake appeared gravid and manual palpation indicated the presence of six eggs. The snake had not undergone ecdysis since capture. Because egg deposition appeared imminent, the snake was offered a plastic box tightly packed with damp sphagnum moss. The snake immediately entered the plastic shoe box and hollowed out an area near the bottom of the container. During the night (approximately 8–10 h after the plastic shoe box was made available), oviposition occurred. A total of six eggs were laid, but one was identified as infertile and did not hatch. The six eggs were incubated at 26–28ºC for ca. 9 weeks in a dampened mixture (3:2) of perlite and vermiculite. One male and four females hatched from the viable eggs.

SENTICOLIS TRIASPIS (Green Rat Snake)**. MAXIMUM SIZE**. The maximum size attained by *Senticolis triaspis* is 1147 mm TL for females and 1213 mm TL for males (Lemos-Espinal and Smith 2007. Amphibians and Reptiles of the State of Chihuahua, México. Universidad Nacional Autónoma de México–Comisión Nacional para el Conocimiento y Uso de la Biodiversidad. 613 pp.). However, Vázquez and Quintero (2005. Anfibios y Reptiles de Aguascalientes. Comisión Nacional para el Conocimiento y Uso de la Biodiversidad. 318 pp.) comment that this species exceeds 1500 mm TL, though they do not provide an exact length or cite a specimen.

On 29 June 2007 we captured an adult female *Senticolis triaspis* in Ejido El Tepeyac (18.4877°N, 96.8535°W; WGS84; 94 m), Tlacotepec de Díaz, Puebla, Mexico. The snake was found above a rock in Tropical Semideciduous forest. The specimen was deposited in the Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México (MZFC 20574). The specimen measured 1500 mm SVL and 1830 mm TL and represents the maximum size recorded for this species.

Submitted by **URI OMAR GARCÍA-VÁZQUEZ,** Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, Apartado Postal 70-399, México, Distrito Federal 04510, México (e-mail: urigarcia@gmail.com); **JOSE LUIS AGUILAR-LOPEZ, ROSAURA VALDEZ-LARES,** Departamento de Biodiversidad y Ecología Animal, Instituto de Ecología A.C., CP 91070 Xalapa, Veracruz, México; and **JONATHAN MACEDA-CRUZ,** Laboratorio de Herpetología, Instituto de Biología, Universidad Nacional Autónoma de México, México, Distrito Federal 04510, México.

SISTRURUS CATENATUS CATENATUS (Eastern Massasauga). **DIET.** Several studies report an ontogenetic dietary shift in *Sistrurus catenatus catenatus* with young age classes consuming snakes and older classes consuming small mammals (Holycross and Mackessy 2002. J. Herpetol. 36:454–464, and citations therein). Shepard et al. (2004. Am. Midl. Nat. 152:360–368) report that snakes were consumed by captive young of the year (YOY) *S. c. catenatus* in every case in which they were offered, but were not found in the stomach contents of free ranging YOY *S. c. catenatus* examined in southern Illinois. The following observations were made in the course of conducting a radio-telemetry study of YOY *S. c. catenatus* along the Upper Wapsipinicon River, Bremer County, Iowa, USA.

On 4 September 2007 at 1025 h, we captured a YOY male *S. c. catenatus* (188 mm SVL; 10 g) consuming a small snake, with only the tail still visible. The *S. c. catenatus* was retained for transmitter attachment and ca. three hours later it regurgitated an intact and undigested YOY *Opheodrys vernalis* (100 mm SVL; 2 g). On 15 September 2007, a second young of the year male *S. c. catenatus* (254 mm SVL; 35 g) was captured and also retained for transmitter attachment. Prior to release, it defecated and the feces contained snake skin, which we later identified as *O. vernalis* based on the presence of smooth scales (*O. vernalis* is the only snake species present at the study site possessing smooth scales). On 9 May 2006 at 1535 h, we found a previously marked subadult female *S. c. catenatus* (434 mm SVL; 100 g) basking in full sunlight with a large bulge at mid-body. While collecting morphological data, she regurgitated an intact and undigested *Microtus pennsylvanicus* (155 mm total length, 55 g). The relative prey mass (RPM; prey mass/ snake mass) was 0.55, similar to the mean mass ratio of 0.47 reported by Shepard et al. (2004. *op. cit*.) for free-ranging YOY *S. c. catenatus* in Illinois.

Mauger and Wilson (1999. *In* Johnson and Wright [eds.] Second International Symposium and Workshop on the Conservation of the Eastern Massasauga Rattlesnake, pp. 110–124. Toronto Zoo, Ontario) previously reported *O. vernalis* in the diet of two subadult (50–150 g) *S. c. catenatus* from northeastern Illinois. Ours is the second report of *O. vernalis* in the diet of *S. c. catenatus* (Holycross and Mackessy 2002, *op. cit*.) and the first in this size class. The observations reported here provide further evidence of an ontogenetic dietary shift in *S. c. catenatus*.

We thank the U.S. Fish and Wildlife Service and the Iowa Department of Natural Resources for funding.

SISTRURUS CATENATUS CATENATUS (Eastern Massasauga). **LEIOMYOMA**. Leiomyomas are benign, smooth muscle tumors usually arising from the gastrointestinal or female reproductive tract. We know of no report of this tumor in snakes although one of us has seen leiomyosarcoma in *Bogertophis subocularis* (Trans Pecos Ratsnake; ERJ, unpubl.). Leiomyosarcoma has been reported in a *Drymarchon corais erebennus* (Texas Indigo Snake) by Barten (1981. J. Amer. Vet. Med. Assoc. 179:1292–1295) and leiomyoma has been reported in a *Chelonia mydas* (Green Turtle) where it caused intestinal stricture (Helmick et al. 2000. J. Zoo Wildl. Med. 31:221–227). Here we report a large leiomyoma that appears to have caused the death of a captive *Sistrurus catenatus catenatus* (Eastern Massasauga). This appears to be the first report of any form of leiomyoma in a crotalid snake.

This 11-year-old snake (Drake University Research Collection, DURC 3913) was born 12 August 1972 shortly after the mother (DURC 3912) was captured by JLC on 25 June 1972 in Bremer County, Iowa. The specimen ate well until two months before its death approximately 2 January 1983 and appeared to be robust. Upon its death, the snake was preserved and placed in the Drake University Research Collection. Upon examination (during the course of conducting a reproductive study) the snake (ca. 570 mm TL) was found to have a large (ca. 154 × 27 mm) mass paralleling the atrophied intestinal tract and had almost no fat.

The mass was sectioned at both ends and routinely processed for light microscopy. Paraffin embedded 7 μm sections were stained with hematoxylin and eosin and examined. The mass consisted of interlacing bundles of spindle-shaped cells with an eosinophilic staining cytoplasm; cells were oriented in different planes. The nuclei were often elongate and had round to blunt ends and a distinct nucleolus was present. Sections stained with Mallory's trichrome stain did not show connective tissue (collagen) and no mitotic figures were seen. Scattered among the tumor cells were cross sections of blood vessels. There was no evidence of necrosis, invasion, or metastasis (Fig. 1).

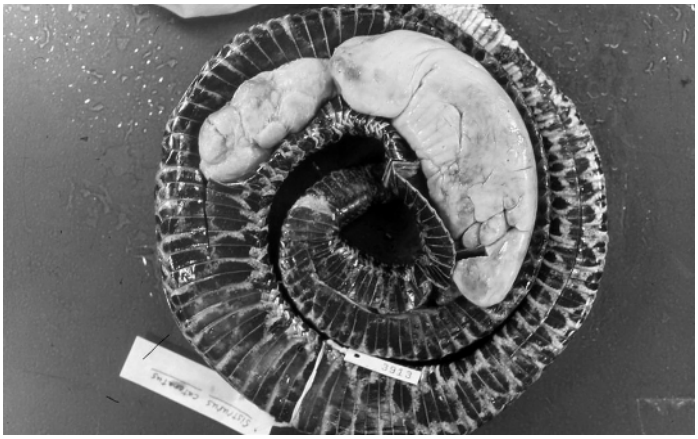

FIG. 1. *Sistrurus catenatus catenatus*, DURC 3912, with very large exposed leiomyoma that apparently caused the death of the snake.

The presentation is consistent with a leiomyoma. Origin of the tumor is uncertain because of local tissue atrophy and poor tissue preservation in the region, but we suspect it arose from the gastrointestinal tract. Although the mass was submitted for immunohistochemical staining for actin to further confirm the diagnosis, it was lost in shipment and special staining was not possible. We suspect that the tumor eventually disrupted passage through the intestine resulting in intestinal atrophy.

In addition to the tumor, scattered ovarian tissue was found attached to the coleomic wall in several places. This too was sectioned and found to consist of multiple vitellogenic and atretic follicles. The ovarian tissue was surrounded with a mix of macrophages, small round cells, and heterophils. This condition, yolk peritonitis, is not uncommon in reptiles and is seen when yolk is released from the reproductive tract or when follicles rupture and release yolk into the coelomic cavity (Mader 2006. *In* D. R. Mader [ed.], Reptile Medicine and Surgery, pp. 581–630. Sauders, Elsevier. St Louis, Missouri).

THAMNOPHIS ELEGANS ELEGANS (Mountain Garter Snake). **PREDATION**. *Thamnophis elegans* has one of the largest geographic ranges of any *Thamnophis* (Stebbins 2003. Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, New York, New York. 519 pp.). As a consequence, it takes a wide variety of prey, including mammals, birds, reptiles, amphibians, fishes, and invertebrates, including annelids and mollusks (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp., and citations therein). Reflecting this diverse range of prey are the methods used to procure it (Drummond and Burghardt 1983. Behav. Ecol. Sociobiol. 12:43–48). Though *T. elegans* typically swallows its prey alive, as do other *Thamnophis*, alternate methods of killing prey, such as constriction, have been reported (Peterson 1978. Am. Zool. 18:649; Gregory et al. 1980. Herpetologica 36:87–93; de Queiroz and Groen 2001. J. Herpetol. 35:450–460). One infrequently reported method of killing prey is envenomation. Here, we report the apparent envenomation of an Oregon Vole (*Microtus oregoni*; Ingles 1995. Mammals of the Pacific States. Stanford University Press, Stanford, California. 506 pp.) by a *T. e. elegans*.

At 1200 h on 19 September 2007, we were searching the bank of the North Santiam River (Marion County, Oregon, USA; 44.7580°N, 122.3927°E, 277 m elev.; WGS84) for snakes when we heard squeaking coming from a clump of sedges (*Carex* sp.) at the river's edge. Investigation revealed an adult female *T. e. elegans* (564 mm SVL, 726 mm total, 90 g) attacking an adult (ca. 90 mm) *M. oregoni*. At first, the snake's head and the vole were hidden, though movement of the sedges revealed their position. The snake's body and tail were wrapped around stems, presumably to improve its grip. Within 90 sec, the squeaking stopped, and the snake pulled the now lifeless vole out of the sedges. The snake, which had a firm grip on the vole's back, just above the hind legs, began swallowing it tail first. Swallowing took 80 minutes and once it was completed, the snake was captured, measured, and held for six days. It then defecated and was released. Examination revealed the upper and lower mandibles (with teeth) to be the only undigested parts of the vole.

Besides documenting an unrecorded prey species for *T. e. elegans*, two aspects of this observation merit comment: 1) the way in which the snake captured the vole; and 2) the rapidity with which the vole succumbed. The fact that the snake's body was stretched out during the capture and handling of the vole eliminates constriction as a possibility. The undisturbed condition of the vole's fur suggests that the snake did not shift its hold during the encounter. In field observations of Common Garter Snakes (*Thamnophis sirtalis*) capturing and consuming rodents (*Microtus* spp.) under similar situations, the rodents were simply swallowed whole and remained alive while being consumed (C. Rombough, pers. obs.). Therefore, considering the relatively rapid death (< 90 sec) of the vole in this situation, as well as the circumstances under which it was captured and consumed, it seems most likely that the snake's saliva was the cause of mortality. *T. elegans* is known to produce toxic saliva (Kardong 1980. Amer. Zool. 20:269–282; Vest 1981. Toxicon 19:831–839; Jansen 1987. J. Herpetol. 21:81–83), and in at least one other instance, has been observed envenomating mammal prey (St. John 2002. Reptiles of the Northwest. Lone Pine, Auburn, Washington. 272 pp.). The diversity of prey taken, along with the regional variation in foraging and methods of prey capture by *T. elegans*, suggest that envenomation may be a locally important means of taking prey, although more observations are needed to clarify its significance.

We thank B. Coblentz, D. Knutsen, M. Hayes, and A. St. John for assistance.

Submitted by **CHRISTOPHER J. ROMBOUGH**, Rombough Biological, 2545 Columbia Blvd., #64, St. Helens, Oregon

97051, USA (e-mail: rambo2718@yahoo.com); and **MARK V. LEPPIN,** 1011 Parkway Drive NW, Salem, Oregon 97304, USA (e-mail: arborealboids@yahoo.com).

THAMNOPHIS ELEGANS (Western Terrestrial Gartersnake). **ELEVATION.** The high elevation record for *Thamnophis elegans* is often reported as ca. 3990 m (13,100 ft) based on two specimens (MCZ 62473 and 62474), both collected 15 August 1960 in San Miguel County, Colorado (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. 3rd edition. Houghton Mifflin Company, Boston, Massachusetts. 533 pp.; Hammerson 1999. Amphibians and Reptiles in Colorado. University Press of Colorado, Niwot, Colorado. 484 pp.; Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. University of Oklahoma Press, Norman, Oklahoma. 332 pp.). There are no field notes associated with these specimens. However, catalog records indicate that the collector traveled through Utah, Colorado, Wyoming, and New Mexico during July and August of 1960. These two specimens are the only specimens he collected in Colorado. Although the catalog entry states "13,100 +/-," the fairly explicit collection locality associated with both specimens is "Colorado: Old Ophir nr. Telluride." The town site of Old Ophir (37.8566°N, 107.8319°W) is in a high valley at ca. 2974 m (9756 ft) elevation. The only road through Old Ophir reaches its highest elevation in nearby Ophir Pass at 3593 m (11,789 ft). In our view, the elevation associated with these specimens is somewhat questionable.

Hendricks (Herpetol. Rev. 27:89) obtained a more reliable record than those above with his report of a *T. elegans* (Idaho Museum of Natural History Photofile, IMNHP 001) at 3182 m (10,440 ft) on the Beartooth Plateau in Park County, Wyoming that was 155 m above tree line and within Alpine Tundra habitat. At 1612 h on 01 September 2007 we found a *T. elegans* at 3658 m (12,002 ft) on Humphrey's Peak, San Francisco Peaks, Coconino County, Arizona, USA. The snake was found in Alpine Tundra (ca. 150 m above treeline) along the ridgeline (35.339056°N, 111.683878°W) between Humphrey's Peak and the saddle with Agassiz Peak. A photographic voucher is deposited at the University of Arizona (UAZ 56926-PSV). This observation might represent the high elevation record for *T. elegans* throughout its range and it is the highest elevation reported for any reptile in Arizona (A. T. Holycross, pers. comm.).

We thank J. Rosado for providing information on the specimens deposited in the Museum of Comparative Zoology at Harvard University.

BOKERMANNOHYLA CARAMASCHII (NCN). BRAZIL: BAHIA: Municipality of Camacan, Serra Bonita Reserve (15.3916667ºS, 39.5652778ºW) 850 m elev. 15 March 2008. M. Solé. Verified by J. Faivovich and A. C. C. Lourenço. Coleção Célio Fernando Baptista Haddad, Departamento de Zoologia, Universidade Estadual Paulista, Rio Claro, SP, Brazil (CFBH 19561–62) and Coleção Herpetologica do Museu Nacional, Rio de Janeiro, RJ, Brazil (MNRJ 51716). This species has only been previously recorded from the northern sector of the Serra da Mantiqueira in Espírito Santo and Minas Gerais States, Brazil (Napoli 2005. Herpetologica 61[1]:63–69). First record for the state of Bahia, extending the previously known distribution 510 km N from Santa Teresa, Espírito Santo state (type locality)

Submitted by **VICTOR GOYANNES DILL ORRICO**, Departamento de Zoologia, Instituto de Biociências, Universidade Estadual Paulista, CEP 13506-900, Rio Claro, SP, Brazil (e-mail:

victordill@gmail.com); and **MIRCO SOLÉ**, Departamento de Ciências Biológicas, Universidade Estadual de Santa Cruz, Rodovia Ilhéus-Itabuna, km 16, CEP 45662-000, Ilhéus, BA, Brazil (e-mail: mksole@uesc.br).

CHIASMOCLEIS ALBOPUNCTATA (NCN). PARAGUAY: CENTRAL DEPARTMENT: Municipality of Mariano Roque Alonso, Surubií Urbanization (25.18667ºS, 57.513889ºW, WGS 84). 07 March 2008. S. Vargas. Colección Biológica Arnoldo da Winkelried Bertoni-Instituto de Investigación Biológica del Paraguay (IIBP-H 600). Verified by E. O. Lavilla. This is the first record with voucher for the Central Department and southernmost locality for this species, which was previously known from the Department of Santa Cruz in eastern Bolivia (De la Riva et al. 2000. Rev. Esp. Herpetol. 14:19–164; Frost 2007. Amphibian Species of the World: An Online Reference. V 5.1 [March 2008]. http://research.amnh.org/herpetology/amphibia/index.php); and from the states of Goiás, Mato Grosso, Mato Grosso do Sul, Minas Gerais, and São Paulo in Brazil (Frost, *op. cit.*). In Paraguay it has been registered in the Departments of Alto Paraguay, Amambay, Canindeyú, and Concepción (Brusquetti and Lavilla 2006. Cuad. Herpetol. 20[2]:3–79) in the northern part of the country. Two authors previously cited this species from Asunción in the Central Department as *Engystoma albopunctatum*, but without vouchers (Boulenger 1894. Ann. Mag. Nat. Hist. 13[6]:342–348; Bertoni 1939. Rev. Soc. Cient. Paraguay 4[4]:42–43). The present locality is in the Humid Chaco ecorregion (following Dinerstein et al. 1995. Una Evaluación del Estado de Conservación de las Ecorregiones Terrestres de América Latina y el Caribe. WMF-Banco Mundial) and extends the range ca. 236 km SW from the previously cited southernmost locality in the Canindeyú Department, Estancia Rama III near Mbaracayú Reserve (Brusquetti and Lavilla, *op. cit.*).

Submitted by **FRANCISCO BRUSQUETTI** (e-mail: franbrusquetti@gmail.com) and **FLAVIA NETTO** (e-mail: e-mail: flanettosisa@gmail.com), Instituto de Investigación Biológica del Paraguay (IIBP) – Del Escudo 1607. 1429 – Asunción, Paraguay.

DENDROPHRYNISCUS CARVALHOI (Sapinho-arborícola; Carvalho's Tree Toad). BRAZIL: ESPÍRITO SANTO: Ibitirama municipality: Santa Marta district: Fazenda Pico da Bandeira: Parque Nacional do Caparaó (20.467222°S, 41.733889°W; WGS84; elev. 1135 m). 07 November 2005. M. T. Rodrigues and J. Cassimiro. Museu de Zoologia da Universidade de São Paulo, São Paulo, Brazil (MZUSP 135662–64; M. T. Rodrigues field number MTR 11565, 11584–85, respectively); 01 November 2006. M. T. Rodrigues, J. Cassimiro, and V. K. Verdade. (MZUSP 139103; M. T. Rodrigues field number MTR 12622). Verified by D. Pavan. Previously known only from the type locality: Santa Tereza municipality, Espírito Santo state, southeastern Brazil (Izecksohn 1994 "1993." Rev. Brasil. Zool. 10:473–488) and included in the IUCN Red List of Threatened Species as "endangered" (Silvano and Peixoto 2004. *In* IUCN 2007. 2007 IUCN Red List of Threatened Species. Electronic database available at www.iucnredlist.org. Downloaded on 11 April 2008). These are the most inland records for the species and extend known distribution ca. 130 km airline SW from Santa Tereza municipality, Espírito Santo state (Izecksohn, *op. cit.*).

ELEUTHERODACTYLUS* (= *SYRRHOPHUS*) *MARNOCKII (Cliff Chirping Frog). USA: TEXAS Crockett Co.: 14.6 km E of Sheffield on State Highway 290. 05 June 2008. Brandon D. Pope and Robert Makowsky. The University at Arlington Amphibian and Reptile Diversity Research Center Collection (UTA A 58666). Verified by Carl J. Franklin. First record for this county (Dixon 2000. Amphibians and Reptiles of Texas. 2nd Edition. Texas A&M University Press. College Station, Texas. 432 pp.). The specimen was collected at 2130 h on the side of a vertical rock face. There were rainstorms immediately north of the area and conditions were windy.

Submitted by **BRANDON D. POPE,** 1706 Nueces Trail, Arlington, Texas 76012, USA (e-mail: wahoo100@hotmail.com); **COREY E. ROELKE** (e-mail: croelke@uta.edu), and **ROBERT MAKOWSKY** (e-mail: makowsky@uta.edu), Department of Biology, the University of Texas at Arlington, Box 19498, Arlington, Texas 76019, USA.

ELEUTHERODACTYLUS* (*EUHYAS*) *PLANIROSTRIS (Greenhouse Frog). HONDURAS: CORTES: San Pedro Sula, (15.32164°N, 88.00348°W), 100 m elev. 28 August 2007. Franklin E. Castañeda, Juan Ramon Collart, James R. McCranie, and José Mario Solis. Verified by Steve W. Gotte. USNM 565143–48. First record for Honduras (McCranie and Castañeda 2007. Guía de Campo de los Anfibios de Honduras. Bibliomania, Salt Lake City, Utah. x + 304 pp). The presence of adults, including calling males, and juveniles of this exotic species indicate an established population in San Pedro Sula. Frogs reported herein were collected in and around potted plants in the yard of a private residence. Ancestors most likely arrived in potted plants imported from Miami, Florida, because information from the nursery where the potted plants were purchased indicated most come from Miami.

Submitted by **JAMES R. McCRANIE**, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **JUAN RAMON COLLART**, San Pedro Sula, Honduras (e-mail: jrcollart@gmail.com); and **FRANKLIN E. CASTAÑEDA**

LITHOBATES AREOLATA (Crawfish Frog). USA. TENNESSEE: Henderson Co.: Westwood Acres subdivision, Scotts Hill Quad (35.51663°N, 88.26262°W, NAD 83). 17 March 2008. Chad Harden. Austin Peay State University Museum of Zoology (APSU 18893). Multiple individual Crawfish Frogs recorded as they called from streams and ponds along JoAnn Drive and Westwood Acres Road. New county record that extends the range in Tennessee into the southeastern portion of Henderson County (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Hard copy and Internet versions, the latter of which includes links to information on Tennessee herpetology having appeared since 1996 [http://www.apsu.edu/amatlas/, accessed 28 March 2008]). Gibson Co.: Holly Leaf community 3.8 miles ESE of Skullbone on Highway 105 in the Trezevant West Quad (35.029000°N, 89.265350°W; NAD 83). 20 March 2008. Andy Rutherford. APSU 18894. Crawfish Frog recordings collected at farm pond north of Highway 105 and south of South Fork Obion River. Specimens verified by A. Floyd Scott.

Voucher recording collection made under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

Submitted by **CHAD HARDEN**, Tennessee Wildlife Resources Agency Region I, 200 Lowell Thomas Drive, Jackson, Tennessee 38301, USA; e-mail: chad.harden@state.tn.us.

LITHOBATES SPHENOCEPHALUS (= RANA SPHENOCEPHALA) (Southern Leopard Frog). USA: TEXAS: Hays Co.: 1 km SW jct South Turnersville Road and Satterwhite Road, on Satterwhite Road (30.05649°N, 097.77151°W; WGS 84). 20 February 2008. Vincent R. Farallo, Romey Swanson, Jeff Troy, and Glen Hood. Verified by Toby Hibbitts, Texas Cooperative Wildlife Collection (TCWC 93002, 93003). Two individuals were captured by hand, representing the first recorded occurrence of this species in Hays County (Dixon 2000. Amphibians and Reptiles of Texas: With Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Publ. Texas A&M University Press. 421 pp.).

Submitted by **VINCENT R. FARALLO** (e-mail: VF1030@txstate.edu), **ROMEY SWANSON**, **JEFF R. TROY**, **GLEN R. HOOD**, and **MICHAEL R.J. FORSTNER**, Department of Biology, Texas State University, San Marcos, Texas 78666, USA.

PSEUDACRIS FERIARUM (Upland Chorus Frog). USA: TENNESSEE: Jefferson Co.: 12.7 km W of Jefferson City (36.107533°N, 83.625167°W). 22 March 2008. Ted M. Faust. Verified by Floyd A. Scott. Austin Peay State University Museum of Zoology (APSU 18898, 18899 [color photo]). An amplexed pair was found in a drainage ditch in an open field at 1245 h. Many others were heard calling in the immediate area. New county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Hard copy and Internet versions, the latter [http://www.apsu.edu/amatlas/ accessed 23 March 2008] including links to data on amphibians in Tennessee that have appeared since 1996).

***PYXICEPHALUS* SP**. (NCN): REPUBLIC OF NIGER: AGADEZ REGION, Tasaouet Valley (17.40473ºN, 007.52751ºE), ca. 450 m elev. 15 March 2003. J. Sébastien Steyer. University of Washington, Burke Museum of Natural History (UWBM),

Seattle, Washington, USA. UWBM 2319. Verified by Marc Hayes. *Pyxicephalus* is known from southern and central Africa (*P. adspersus, P. edulis*) and Somalia (*P. obbianus*). In western Africa, documented in northernmost Cameroon (Perret 1966. Zool. Jahr. Syst. 8:289–464; Amiet 1973. Ann. Fac. Sci. Cam. 12:63–78), northern Nigeria (Schiøtz 1963. Vidensk. Medd. Fra Dansk Naturh. Foren. 125:1–92; Walker 1968. Copeia 1968:164–167), northern Benin (Nago et al. 2006. Salamandra 42:93–108), Senegal (Böhme et al. 2001. Zeit. Köl. Zoo 44:117–131), Gambia (Emms et al. 2006. Herpetol. Bull. 94:6–16), and southernmost Mauritania (Böhme et al. 2001. Zeit. Köl. Zoo 44: 117–131; Padial and De la Riva 2004. Rev. Esp. Herpetol. 18:89–99). These records are attributed to *P. edulis*, but taxonomic status of western populations are unclear. UWBM (head length ca. 31.9 mm) is a desiccated specimen and skeleton posterior to sacral vertebra missing, remaining skeleton mostly articulated with some associated skin and flesh. Collected from sand at base of rock face at western edge of Aïr Mountains. Among African frogs, specimen identifiable as *Pyxicephalus* by well developed exostosis of the dermal skull bones and by tight articulation between anterior ramus of squamosal and dorsal surface of maxilla (Scott 2005. Cladistics 21:507–574). Record extends range of genus in three important ways. First record from Saharan Desert and suggests its occurrence in other areas of Sahara with permanent or somewhat regular seasonal precipitation, including Adrar des Iforhas in northern Mali or Adrar in northern Mauritania. Northernmost record for genus, surpassing record from Ayoûn El Atroûs (Wilaya Hodh El Gharbi) in Mauritania (Padial and De la Riva 2004). Nearest known population of *Pyxicephalus* in Rimi in northern Nigeria, and thus this record extends range of genus > 500 km north at this longitude.

Submitted by **DAVID C. BLACKBURN**, Department of Organismic and Evolutionary Biology, Harvard University, 26 Oxford Street, Museum of Comparative Zoology, Cambridge, Massachusetts 02138, USA; e-mail: david.c.blackburn@gmail.com.

RHACOPHORUS MAXIMUS (Nepal Flying Frog): VIETNAM: BAC GIANG PROVINCE: Son Dong District: Thanh Luan Commune: Dong Ri (21.10665ºN, 106.47.950ºE, ca. 280 m elev., IEBR 3653), 10 May 2008; and Thanh Son Commune: Dong Thong (21.11131ºN, 106.43411ºE, 250 m elev., IEBR 3677–81), 12–13 May 2008. T. Q. Nguyen, T. T. Tran, C. T. Pham and N. H. Vi. Found both on tree (ca. 1–2 m above ground) and in small ponds in secondary forest. Verified by Thomas Ziegler. Outside of Vietnam, this species is known from northeastern India, Nepal, southern China, and western Thailand (Ahl 1931. Das Tierreich 55:169; Inger 1966. Fieldiana Zool. 52:321; Zhao and Adler 1993. Herptology of China. SSAR, Oxford, Ohio. 522 pp.; Chanard 2003. Photographic Guide to Amphibians of Thailand: 144). First country record for Vietnam. Orlov et al. (2008. Russian J. Herpetol. 15[1]:78) include this species in the amphibian fauna of Vietnam, but without reference to precise locality or voucher specimens.

Submitted by **NGUYEN THIEN TAO**, Vietnam National Museum of Nature, 18 Hoang Quoc Viet, Hanoi, Vietnam **TRAN THANH TUNG**, Education College of Vinh Phuc, Phuc Yen, Vinh Phuc, Vietnam; **NGUYEN QUANG TRUONG** and **PHAM THE CUONG**, Institute of Ecology and Biological Resources, 18 Hoang Quoc Viet, Hanoi, Vietnam (e-mail: nguyenthientao@gmail.com).

RHACOPHORUS RHODOPUS (Red-webbed Tree Frog): VIETNAM: BAC GIANG PROVINCE: Son Dong District: Thanh Son Commune: Dong Thong (21.11131°N, 106.43411ºE, 250 m elev., IEBR 3675–76), 12–13 May 2008. T. Q. Nguyen, T. T. Tran, C. T. Pham, and N. H. Vi. Found on tree (ca. 1–2 m above ground) near small pond in secondary forest. Verified by Thomas Ziegler. Known from Lao Cai, Ha Tinh, Quang Binh, Quang Tri, Thua Thien-Hue, Kon Tum, Gia Lai, Lam Dong, and Dong Nai provinces of Vietnam; and extralimitally, northeastern India, southern China, Myanmar, Laos, northern Thailand, and Cambodia (Zhao and Adler 1993. Herptol of China. SSAR, Oxford, Ohio. 522 pp.; Inger et al. 1999. Fieldiana Zool. 92:33; Nguyen et al. 2005. Checklist of Amphibians and Reptiles of Vietnam. Agri. Publ. House, p. 39; Orlov et al. 2002. Russian J. Herpetol. 9[2]:97; Ziegler et al. 2004. Hamadryad 28[1–2]:31; Stuart 2005. Herpetol. Rev. 36:478; Bain et al. 2007. Herpetol. Rev. 38:111; Bordoloi et al. 2007. Zootaxa 1653:5; Grismer et al. 2007. Hamadryad 31[2]:221). Bordoloi et al. (2007, *op. cit.*) proposed to used the name *Rhacophorus rhodopus* for the brown-backed form and *R. bipunctatus* for frogs of green-backed populations. Therefore, previous records of *R. bipunctatus* in Vietnam should be referred to *R. rhodopus*. First provincial record.

MACROCLEMYS TEMMINCKII (Alligator Snapping Turtle). USA: TENNESSEE: Wayne Co.: Beech Creek and Tennessee River confluence located in the Clifton Quad (35.41980°N, 87.98018°W; NAD 83). August 2006. Mark Russell. Austin Peay State University Museum of Zoology (APSU 18868). Verified by A. Floyd Scott. One adult *M. temminckii* found dead on the river bank at the mouth of Beech Creek. Carapace length 62.2 cm. First record for Wayne County (Redmond and Scott 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available from http://apsu.edu/reptiles/) accessed 28 January 2008.

Voucher collection made under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

Submitted by **CHAD HARDEN**, Tennessee Wildlife Resources Agency, 200 Lowell Thomas Drive, Jackson, Tennessee 38301, USA; e-mail: chad.harden@state.tn.us.

MALACLEMYS TERRAPIN CENTRATA (Carolina Diamondbacked Terrapin). USA: GEORGIA: Bryan Co.: Demeries Creek, 0.4 km W of Bryan Neck Rd. (31.7872056°N, 81.2560333°W, WGS 84). 09 April 2008. Andrew M. Grosse, Andrew Richard Ferreira, and Sean C. Sterrett. Verified by John Jensen. UGAMNH (GMNH 50090). New county record (Spivey 2008. *In* J. B. Jensen et al. [eds.], Amphibians and Reptiles of Georgia, pp. 485–487. University of Georgia Press, Athens, Georgia). Eight adults (7 males, 1 female) were captured by seining (11 m × 1.8 m, 2.54 cm mesh, with bag) a tidally influenced creek at low tide (methods in Gibbons et al. 2001. Chel. Cons. Biol. 4:66–74). This location was revisited on 27 April 2008, and 8 additional terrapins (7 males, 1 female) were captured. Although only 16 *M. terrapin* were captured, observations of other individuals were made within the same creek. On 22 April 2008, nine individuals (8 males, 1 female) were captured in another tidally influenced creek in Bryan County (north of Dutchman Bay, 2.5 km SW of Belfast, Georgia; 31.8018694°N, 81.2974361°W, WGS 84) using the same methods. These findings suggest that Carolina Diamondback Terrapins are permanent inhabitants of Bryan County and with this addition, their range extends along the entire coast of Georgia.

SQUAMATA –LIZARDS

ANOLIS* (=*NOROPS*) *SAGREI (Brown Anole). USA: FLORIDA: Leon Co.: Tallahassee. 28 May 2008. D. B. Means, R. C. Means, R. P. M. Means. Verified by Kenneth L. Krysko, Florida Museum of Natural History. One male from 2121 NE Capital Circle (UF 152949); two males from 2748 NE Capital Circle (UF 152947–8); and one male from 3151 Capital Circle NE (UF 152950). New county record, extending the range about 120 km NE from the closest known population on St. George Island, Franklin Co., Florida (Means 1996. Herpetol. Rev. 27:151–152; Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida). The voucher specimens were taken along a 1.5 km stretch of NE Capital Circle from the 2100 block (30.4813889ºN, 84.235ºW, 24 m elev.) to the 3300 block (30.4986111ºN and 84.2466667ºW, 59 m elevation) at the same time that 15 additional *A. sagrei* ranging from juveniles to adults of both sexes were seen basking in sunlight or facing downward on fence posts, trees, shrubs, and other structures. One of us observed *A. sagrei* at 2121 NE Capital Circle in 2004, but none was captured at that time. Local residents tell us that individuals are abundant more than two city blocks to the east and west of Capital Circle NE. Capital Circle NE is an urban commercial area with suburban residential streets paralleling it. Brown Anoles could have been imported in potted plants sold by three large nurseries along this street. One adult male Green Anole (*A. carolinensis*) was seen at the 2748 NE Capital Circle locality on 28 May 2008. On 13 June 2008, DBM visited a fourth commercial nursery at 2911 Thomasville Road, Tallahassee, Florida, ca. 1.5 km SE of our 3151 Capital Circle NE record, and saw three *A. sagrei* on small trees. Nursery workers said that they have seen the Brown Anole there since 1999. These records are important in determining the chronology of the geographic expansion of an invasive species.

Submitted by **D. BRUCE MEANS, RYAN C. MEANS**, and **REBECCA PHARR MEEGAN MEANS,** Coastal Plains Institute and Land Conservancy, 1313 Milton Street, Tallahassee, Florida 32303, USA; e-mail: means@bio.fsu.edu.

ANOLIS* (= *NOROPS*) *SAGREI (Brown Anole). USA: LOUISIANA: Calcasieu Parish: Lake Charles, Green Gate Garden Center, 4226 Lake St. 24 April 2008. Jay Comeaux. Verified by Jeff Boundy. Louisiana State University at Eunice Vertebrate Collection (LSUE 2841). New parish record. Single adult male was collected although juveniles were also observed on the grounds of the garden center in the vicinity of imported fruit trees. According to the management of the establishment, many of the fruit trees have been obtained from growers in southern Florida. It is likely that this population of Brown Anoles was introduced with the plant material from Florida; seemingly, this is a common mode of introduction into Louisiana for this species (see Thomas et al. 1990. Herpetol. Rev. 21:22; Platt and Fontenot 1994. Herpetol. Rev. 25:33; Boundy 2004. Herpetol. Rev. 35:194–196; and Wiley et al. 2007. Herpetol. Rev. 38:217). Boundy (*op. cit.*) reported the nearest recorded population in Louisiana from Lafayette Parish.

Submitted by **AVERY A. WILLIAMS**, Division of Sciences and Mathematics, Louisiana State University at Eunice, Eunice, Louisiana 70535, USA; and **JAY COMEAUX**, Department of Biological and Environmental Sciences, McNeese State University, Lake Charles, Louisiana 70609, USA.

BASILISCUS VITTATUS (Brown Basilisk). USA: FLORIDA: Indian River Co.: Sebastian Inlet State Park, Coconut Point (27.8510667ºN, 80.453566ºW, WGS84). 09 May 2008. Philip L. Rand. Adult male observed at 0845 h in mangroves at a boat ramp on a barrier island S of Sebastian Inlet. Florida Museum of Natural History photographic voucher (UF 152851). Verified by Kenneth L. Krysko. New county record and extends range ca. 42 km N of a population in St. Lucie Co. (Krysko et al. 2005. Herpetol. Rev. 36:85–87). Another *B. vittatus* was later observed 1 km NE.

Submitted by **PHILIP L. RAND**, Department of Environmental Protection, Sebastian Inlet State Park, 9700 South A1A, Melbourne Beach, Florida 32951, USA; **GRAHAM E. WILLIAMS**, Department of Environmental Protection, Florida Park Service, 1800 Wekiwa Circle, Apopka, Florida 32712, USA; and **KEVIN M. ENGE**, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA (e-mail: philip.rand@dep.state.fl.us).

CHAMAELEO CALYPTRATUS (Veiled Chameleon). USA: FLORIDA: Hendry Co.: La Belle, 635 A Road (26.7061ºN, 81.4277ºW, WGS84). 05 May 2008. Richard D. Bartlett. Four males and one female observed in trees during the daytime. Florida Museum of Natural History photographic voucher (UF 152852). Verified by Kenneth L. Krysko. New county record and extends range ca. 39 km E of a population in Lee County (Krysko et al. 2004. Florida Sci. 67:249–253), which is still extant despite heavy collecting pressure. Hundreds of specimens, mostly neonates, have been collected for the pet trade from the Hendry County population (R. D. Bartlett, pers. comm.).

HEMIDACTYLUS TURCICUS (Mediterranean Gecko). USA: MISSOURI: Cape Girardeau Co.: Cape Girardeau. Two small juveniles (SVL = 23.9 and 24.2 mm) were collected in a basement of the Teamsters Local Union 600 building at 429 N. Broadview, 63701 (37.3127667ºN, 89.5539333ºW). 06 September 2008. Jamie Tucker. Verified by Chris Phillips of the Illinois Natural History Survey, INHS 20940 and INHS 20941. Both individuals were captured between 0930–1000 h on a wet, rainy day. A slightly smaller individual was observed in the basement on 13 December 2007, but was not captured. This location is less than 0.5 km from a commercial/industrial area, which may be the source of introduction to Cape Girardeau. This collection is the second reported occurrence of *H. turcicus* in Missouri; the first was reported from St. Louis County by Bufalino (2004. Herpetol. Rev. 35:188).

Submitted by **MICHAEL S. TAYLOR** and **JAMIE L. TUCKER**, Department of Biology, Southeast Missouri State University, Cape Girardeau, Missouri 63701, USA; e-mail: mtaylor@semo.edu.

HEMIDACTYLUS TURCICUS (Mediterranean Gecko). USA: TEXAS: Caldwell Co.: State Hwy 80, 3.07 km SE of County Line Road (29.862ºN, 97.8663611ºW). 25 February 2008. Romey Swanson, Vincent Farallo, Jeff Troy, and Glen Hood. Verified by Toby Hibbitts, Texas Cooperative Wildlife Collection (TCWC 93009–93012). Four individuals of various sizes were found under lights and caught by hand. These individuals represent the first recorded occurrence of this species in Caldwell County (Dixon 2000. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 421 pp.).

Submited by **ROMEY L. SWANSON (**e-mail: rs56761@txstate.edu), **VINCENT R. FARALLO**, **JEFF R. TROY**, **GLEN R. HOOD**, and **MICHAEL R. J. FORSTNER**, Department of Biology, Texas State University, San Marcos, Texas 78666, USA.

HEMIDACTYLUS TURCICUS (Mediterranean Gecko). USA: TEXAS: Guadalupe Co.: 950 m S jct FM 1978 and Hwy 123 (29.78302°N, 097.94715°W; WGS 84). 25 February 2008. Vincent R. Farallo, Romey L. Swanson, Jeff R. Troy, and Glen R. Hood. Verified by Toby Hibbitts, Texas Cooperative Wildlife Collection (TCWC 93004–93007). Four individuals of various sizes were observed under lights and captured by hand, representing the first recorded occurrence of this species in Guadalupe County (Dixon 2000. Amphibians and Reptiles of Texas: with Keys, Taxonomic Synopses, Bibliography, and Distribution Maps. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **VINCENT R. FARALLO (**e-mail: VF1030@txstate.edu), **ROMEY L. SWANSON**, **JEFF R. TROY**, **GLEN R. HOOD**, and **MICHAEL R. J. FORSTNER**, Department of Biology, Texas State University, San Marcos, Texas 78666, USA.

LEIOCEPHALUS SCHREIBERSII (Red-sided Curlytail Lizard). USA: FLORIDA: Miami-Dade Co.: Homestead, 24305 SW 142 Avenue (25.540744ºN, 80.420585ºW; WGS84; elev. 4 m). 3 May 2008. Kenneth L. Krysko and Joseph P. Burgess. Verified by Kevin M. Enge. Florida Museum of Natural History (UF 152827–28). New county record and extends range of this species 58 km S of closest verified record in Hollywood, Broward County (Townsend et al. 2002. Herpetol. Rev. 33:75). Reports of this species at several sites in northern Miami-Dade Co. (e.g., Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Melbourne, Florida. 166 pp.; Wilson and Porras 1983. Univ. Kansas Mus. Nat. Hist., Spec. Publ. No. 9, 89 pp.) have not been verified nor supported by vouchers. Two adult males collected. Nine other individuals of all size classes observed, suggesting a reproducing established population. We have observed this species at this site since 2002, and it has expanded its range at least one block to the north and west.

Submitted by **KENNETH L. KRYSKO**, Florida Museum of Natural History, Division of Herpetology, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu); and **JOSEPH P. BURGESS**, Florida Department of Environmental Protection, Guana Tolomato Matanzas National Estuarine Research Reserve, 505 Guana River Road, Ponte Vedra, Florida 32082, USA.

LEPIDODACTYLUS LUGUBRIS (Mourning Gecko). MALAYSIA: SARAWAK: Kuching: from grounds of Telang Usan Hotel (01.35ºN, 110.20ºE; WGS84), Photographed by Ruchira Somaweera. 04 May 2008. Adult female (showing lack of hemipenial bulge). USDZ photographic archive, ZRC (IMG) 2.93. First record from Sarawak, and a range extension southwestward on Borneo, ca. 1290 km from Kota Kinabalu. Previous Bornean records, based on presumed naturalized populations, are from Sandakan, Sandakan District (Tan 1993. Checklist of Lizards of Sabah. Sabah Parks Trustees, Kota Kinabalu. [2] + 18 pp., based on FMNH 63632) and Tanjung Aru Beach Resort, Kota Kinabalu, Kota Kinabalu District (ZRC 2.6583, *ex*-ID 8145) both in Sabah and Sintang, Kalimantan Barat Propinsi, Kalimantan, Indonesia (de Rooij 1915. The Reptiles of the Indo-Australian Archipelago. Vol. I. Lacertilia, Chelonia, Emydosauria. E. J. Brill, Leiden. xiv + 384 pp.). Global distribution of species, as presently constituted (as a unisexual-bisexual complex), includes Maldives, the Andaman and Nicobar Islands, Sri Lanka, mainland Southeast Asia, Borneo, Riau Archipelago, Sulawesi, Halmahera, Lesser Sundas, Ternate, New Guinea, eastern Asia, Chagos Archipelago, Philippines, northern Australia, Micronesia, and Fiji. Several populations, believed introduced, are found in Brazil, Colombia, Costa Rica, Ecuador, Galapagos Islands, México, New Caledonia, Nicaragua, Panama, Peru, Suriname, and Hawai'i (Bauer and Henle 1994. Familia Gekkonidae [Reptilia, Sauria]. Part I Australia and Oceania. Das Tierreich 109. Walter de Gruyter, Berlin and New York. xiii + 306 pp.; Brown and Alcala 1978. SAUROMALUS HISPIDUS (Spiny Chuckwalla). MÉXICO: BAJA CALIFORNIA: Isla Rasa: ca. 49 km ESE of Bahía de los Ángeles (28.8246178°N, 112.9806675°W; WGS 84), 3 m elev. 17 May 2006. E. Velarde. Verified by J. Angel Soto-Centeno. San Diego Natural History Museum Herpetological Photo Collection (SDNHM-HerpPC 5208–5216). First record from Isla Rasa (Hollingsworth 1998. Herpetol. Monog.12:38–191). It is unknown if this individual is an isolated record or part of an established population. *Sauromalus hispidus* however does occur on Islas Ángel de La Guarda, 15 km NW and on Isla Las Ánimas (= San Lorenzo Norte), 22 km S of Isla Rasa, respectively. The lizard reported herein was observed near the south shore of the island, among rocky boulders close to stands of Cardon (*Pachycereus pringlei*) and cholla cactus (*Cylindropuntia* sp.).

TROPIDURUS PINIMA. BRAZIL: BAHIA: Rio de Contas (13.566667ºS, 41.8°W; SAD69). D. Vrcibradic. 06 January 2005. Museu de Zoologia da Universidade de São Paulo (MZUSP 98047–8). Verified by Miguel T. Rodrigues. This species was described (as *Tapinurus pinima*) by Rodrigues (1984. Pap. Avul. Zool., São Paulo 35:367–373) from Santo Inácio (11.1°S, 42.716667°W), in the state of Bahia, and was believed to be endemic to the type locality (Rodrigues 2003. *In* I. R. Leal et al. [eds.], Ecologia e Conservação da Caatinga, pp. 181–236. Universidade Federal

de Pernambuco, Recife, Brazil). The present record extends the distribution of this species ca. 290 km to the south.

Submitted by **DAVOR VRCIBRADIC, ANGÉLICA FIGUEIRA FONTES, THAÍS KLAION, ALINE S. DIAS,** and **MONIQUE VAN SLUYS,** Departamento de Ecologia, Universidade do Estado do Rio de Janeiro, Rua São Francisco Xavier 524, Maracanã, 20550-011, Rio de Janeiro, RJ, Brazil.

TROPIDURUS TORQUATUS (Calango, Collared Lizard). BRAZIL: SÃO PAULO: Bertioga municipality: Praia de Itaguaré: Foz do Rio Itaguaré (23.779167°S, 5.968611°E; datum: WGS 84; sea level). 06 April 2008. M. A. Sena and J. G. Silva. Museu de Zoologia da Universidade de São Paulo, São Paulo, Brazil (MZUSP 98079, adult male; M. A. Sena field number MA 3615). Verified by Pedro M. S. Nunes. The range of this species includes Uruguay, Paraguay, Argentina, and Brazil. In Brazil, the species occurs in Cerrado core areas of Minas Gerais, Goiás, Mato Grosso do Sul, Mato Grosso, and Maranhão states; in Cerrado enclaves in the Atlantic Rainforest Domain of São Paulo, Rio de Janeiro, Espírito Santo, and Bahia states; an insular population in Abrolhos archipelago (Bahia state); in coastal sandy areas ("restinga" environments) from Rio de Janeiro to Bahia states; and in open areas of southern Brazil in Rio Grande do Sul and westernmost Santa Catarina and Paraná states (Rodrigues 1987. Arq. Zool., São Paulo 31:105–230; França-e-Souza et al. 2002. Herpetol. Rev. 33:149). *T. torquatus* is extremely abundant in open areas. Although there are numerous records south of Rio de Janeiro, these refer to interior populations which according to Rodrigues (1987, *op. cit.*) show significant morphological differentiation from those occurring along the coast. Despite exhaustive searches performed for several years in "restingas" along the coast (see Rodrigues, *op. cit.*), the species was never recorded in this habitat south of Rio de Janeiro state. This new record extends the known distribution at coastal areas ca. 215 km southwest from Restinga da Marambaia, Rio de Janeiro state (Carvalho and Araújo 2007. Rev. Bras. Biol. 24:786–792). This expansion of distribution, and recent occupation, appears to be the result of human expansion in areas along the coast where the species previously did not occur, or perhaps a consequence of the effects of global warming and climate changes. It is interesting to note that well established populations of this species now also occur near the city of São Paulo and surroundings where there were characteristically absent until a couple of years ago. These findings are very important because this lizard is an aggressive colonizer that can adversely affect native species.

Submitted by **MARCO AURÉLIO DE SENA**, Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, Rua do Matão, 277, sala 234, CEP 05508-900, São Paulo, SP, Brazil (e-mail: mausena@yahoo.com); **JOSÉ CASSIMIRO**, Departamento de Zoologia, Instituto de Biociências, Universidade de São Paulo, Caixa Postal 11.461, CEP 05422-970, São Paulo, SP, Brazil (e-mail: geckoides@yahoo.com.br); **CARLOS JOÃO DAVID** (e-mail: david@uninove.br); **JULIANA GARCIA DA SILVA** Universidade Nove de Julho UNINOVE, Rua Diamantina 302/310, Vila Maria, CEP 02117-310, São Paulo, SP, Brazil (e-mail: jsilva@ispcorp.com); and **MIGUEL TREFAUT RODRIGUES**, Departamento de Zoologia, Instituto de Biociências, Universidade de São Paulo, Caixa Postal 11.461, CEP 05422-970, São Paulo, SP, Brazil (e-mail: mtrodri@usp.br).

UROSAURUS GRACIOSUS (Long-tailed Brush Lizard). MÉXICO: SONORA: Municipio de Hermosillo: Km. 25.5, Calle 36 Norte, carretera a Puerto Libertad (29.05841° N, 111.74275° W; WGS 84), 45 m elev. 16 September 2007. J. H. Valdez-Villavicencio. Herpetological collection of Facultad de Ciencias, Universidad Autónoma de Baja California, Ensenada, Baja California, México (UABC 1748). 12.5 km E of Bahía de Kino Viejo (28.81949°N, 111.80603°W; WGS 84), 5 m elev. 8 October 2007. J. H. Valdez-Villavicencio. UABC 1757. Both verified by Bradford D. Hollingsworth. UABC 1757 represents the southernmost record for the species in Sonora, extending the range ca. 107 km SSE from the closest previous locality, ca. 40 km SE of Puerto Libertad (LACM 126607); UABC 1748 fills the gap between those two localities. Both lizards were found on a small mesquite tree (*Prosopis* sp.) in sparsely vegetated habitat with sandy soil.

CEMOPHORA COCCINEA COPEI (Northern Scarlet Snake). USA: MARYLAND: Worcester Co.: Millville Rd., 2.5 km SW junction with Rt. 12 (38.2174527ºN, 075.4811194ºW; NAD83), DOR 1300 h. 12 June 2004, William L. Grogan, Jr. and Matthew T. Close. Verified by Ned S. Gilmore, Academy of Natural Sciences, Philadelphia (ANSP 36238). A second specimen (TL 57.8 cm) from same locality, DOR 26 July 2005, L. T. Biechele, deposited in the vertebrate collection at Salisbury University. Specimens confirm two prior photographic records from Worcester County (Grogan 1985. Bull. Maryland Herpetol. Soc. 21:74–75; Grogan 1994. Bull. Maryland Herpetol. Soc. 30:27–32), and are only the third and fourth museum records of this species from Delmarva Peninsula (White and White 2002. Amphibians and Reptiles of Delmarva. Tidewater Publishers, Centreville, Maryland. 248 pp.). Both specimens are adult females, ANSP 36238 (TL 56.6 cm) contained 9 fully developed eggs with soft shells. The two earlier Delmarva records were a specimen found ca. 1940 near Salisbury, Wicomico County, adjacent to the NW of Worcester County, commented on by Conant (1958. Copeia 1958:50–52) as there were some inaccuracies about its provenance, etc., in the original report by Fowler (1945. Proc. Biol. Soc. Washington 58:89–90). The only other prior museum record was found in 1963 at Trap Pond, W of Laurel, Sussex County, Delaware. This specimen is still the only record from that state that was finally documented by Arndt (1985. Bull. Maryland Herpetol. Soc. 21:67–73) as it was the basis for the distribution maps of this species in Delaware in Conant's second edition (Conant 1975. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Houghton Mifflin Co., Boston, Massachusetts. 429 pp.) and later editons.

COLUBER* (= *MASTICOPHIS*) *MENTOVARIUS (Neotropical Whipsnake). MEXICO: SONORA: Las Palomas, NW slope of Sierra Azul, Rancho El Aribabi, ca. 27 km ENE Imuris and 57 km S of Arizona/Sonora border (32.82000˚ N, 110.56667˚ W, WGS 84), 1311 m elev. 08 September 2007. Sergio Avila and Carlos Robles Elías. Verified by Jerry D. Johnson. UAZ 56736-PSV. Northernmost locality for this species and extends range 212 km NE of closest known locality, 37 km NE of Nacori Chico, Sonora (Lemos Espinal and Smith 2007. Anfibios y Reptiles del Estado de Chihuahua, México. Universidad Nacional Autónoma de México y CONABIO). Specimen was observed along an ephemeral stream in a mesquite/oak grassland association.

Submitted by **SERGIO AVILA**, Sky Island Alliance, 738 N 5th Ave, Suite 201, Tucson, Arizona, USA (e-mail: Sergio@skyislandalliance.org); **CARLOS ROBLES ELÍAS**, Rancho El Aribabi, Carretera Imuris-Cananea Km 131+900, Imuris, Sonora, Mexico (e-mail: elaribabi@telcel.blackberry.net.mx); and **JAMES C. RORABAUGH**, U.S. Fish and Wildlife Service, 201 N. Bonita Ave., Suite 141, Tucson, Arizona, USA 85745 (e-mail: Jim_Rorabaugh@fws.gov).

CROTALUS ATROX (Western Diamond-backed Rattlesnake). USA: OKLAHOMA: McCurtain Co.: Cedar Creek, 9.7 km N North Pole Store (34.18°N, 94.89°W). 30 May 2008. D. Arbour. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ photographic voucher 31207). First genuine record for the county; a much older record for McCurtain County [Kolb 1946. Oklahoma Game & Fish News 2(10):22], presumably from somewhere near Broken Bow, is

considered questionable (L. J. Vitt, pers. comm.). However, Webb (1970. Reptiles of Oklahoma. Univ. Oklahoma Press, Norman, Oklahoma. 370 pp.) included the older record without actually examining the specimen. In addition, Secor and Carpenter (1984. Oklahoma Herpetol. Soc. Spec. Publ. No. 3:1–57) listed the same as a Distribution of Oklahoma Amphibians and Reptiles by Recorded Sightings (DOKARRS) record with it appearing online (http://www.biosurvey.ou.edu/dbsrch/dokalist.php). Interestingly, this snake has not yet been collected immediately eastward from adjacent Little River and Sevier counties, Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.) nor has it been taken in Bowie, Fannin, Lamar, and Red River counties immediately southward along the Red River in northeastern Texas (Dixon 2000. Amphibians and Reptiles of Texas. Univ. Texas A&M Univ. Press, College Station. 421 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. 437 pp.).

FARANCIA ABACURA REINWARDTII (Western Mudsnake). USA: ARKANSAS: Sevier Co.: off St. Hwy. 70, vic. Cossatot Community College, De Queen (34.025°N, 94.216°W). 30 April 2003. D. Arbour. Verified by S. E. Trauth. Arkansas State University Herpetological Museum (ASUMZ photographic voucher 31223). New county record filling a distributional gap in extreme southwestern Arkansas near previous records from Little River County (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.). This is one of the few records of *F. a. reinwardtii* from the Interior Highlands of the Ouachita foothills (Trauth, et al., *op cit.*).

Submitted by **CHRIS T. McALLISTER**, RapidWrite, 102 Brown Street, Hot Springs National Park, Arkansas 71913, USA (e-mail: drctmcallister@aol.com); **HENRY W. ROBISON**, Department of Biology, Southern Arkansas University, Magnolia, Arkansas 71754, USA (e-mail: hwrobison@saumag.edu); and **DAVID ARBOUR**, De Queen, Arkansas 69337, USA (e-mail: arbour@windstream.net).

FARANCIA ABACURA REINWARDTII (Western Mudsnake). USA: TEXAS: Van Zandt Co.: DOR 59.2 cm SVL snake was found on Van Zandt County Road 2721, 1.28 km N of jct. with US 198, 05 June 2007. The closest permanent body of water to this specimen was a cattle tank within a pasture approximately 30 m away. R. Michael Burger. Verified by Carl J. Franklin. Voucher specimen deposited in University of Texas at Arlington Amphibian and Reptile Diversity Research Center (UTA R 55370). New county record (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed. Univ. of Texas A&M Press, viii+421 pp.).

Submitted by **R. MICHAEL BURGER**, 510 VZCR 2721, Mabank, Texas 75147, USA; e-mail: mvburger@dctexas.net.

FORDONIA LEUCOBALIA (Crab-eating Snake). THAILAND: RANONG PROVINCE: Kraburi District: mangrove forest near Tham Phrakhayang, Phrakhayang Cave (10.33ºN, 98.77ºE). 20 October 2002. M. Sumontha. Chulalongkorn University Museum of Zoology, Bangkok (CUMZ R. 2003.16). Verified by A. Aowphol. Freshly ingested adult male (SVL 409 mm, TL 60 mm) regurgitated by an adult female *Bungarus fasciatus* (released; TL ca. 900 mm) caught at 1930 h. First provincial record. Closest Thai record from Phuket Island (Nabhitabhata et al. "2000" 2004. Checklist of Amphibians and Reptiles in Thailand. Office of Environmental Policy and Planning, Bangkok. 152 pp.; Murphy 2007. Homalopsid Snakes. Evolution in the Mud. Krieger Publ. Co., Malabar, Florida. 146 pp.), ca. 100 km southwards. We thank A. Aowphol and K. Thirakhupt for providing working facilities in their institution.

Submitted by **OLIVIER S. G. PAUWELS**, Département des Vertébrés Récents, Institut Royal des Sciences naturelles de Belgique, Rue Vautier 29, 1000 Brussels, Belgium (e-mail: osgpauwels@yahoo.fr); and **MONTRI SUMONTHA**, Ranong Marine Fisheries Station, 157 M. 1, Saphan-Pla Rd., Paknam, Muang, Ranong 85000, Thailand (e-mail: knotsnake2211@yahoo.com).

HETERODON NASICUS (Plains Hognose Snake). USA: COLORADO: Boulder Co.: Rabbit Mountain Open Space (40.248787°N, 105.224775°W; NAD83). 20 May 2008. Elijah Wostl and Tim Warfel. Photo verified by Lauren J. Livo. University of Colorado Museum Ancillary Collection 166. New County Record (Hammerson 1999. Amphibians and Reptiles of Colorado. 2nd ed. University Press of Colorado, Niwot. 424 pp.).

HYDROMORPHUS CONCOLOR (Serpiente Acuática). PANAMÁ: PANAMÁ: Distrito de Chimán: Pacific slope of Serranía de Majé (8.8664°N, 78.5871°W; WGS84), 505 m elev. 17 March 2004. Marcos Ponce A. Verified by Mahmood Sasa. Museo de Vertebrados de la Universidad de Panamá (MVUP 1889). New district record, extending the geographic range ca. 98 km (airline) SE of the nearest locality in central Panamá (Ibáñez et al. "1994"[1995]. Scientia (Panamá) 9:17–31).

Submitted by **MARCOS PONCE A.**[1], **FRANK A. SOLÍS**[2,3], **ROBERTO IBÁÑEZ D.**[2,3,4] ,and **CÉSAR A. JARAMILLO A.**[2,4,5]. [1]Instituto de Ciencias Ambientales y Desarrollo Sostenible, Universidad Autónoma de Chiriquí, David, Rep. de Panamá; [2]Círculo Herpetológico de Panamá, Apartado 0824-00122, Panamá, Rep. de Panamá; [3]Departamento de Zoología, Universidad de Panamá, Panamá, Rep. de Panamá; [4]Smithsonian Tropical Research Institute, Unit 0948, APO AA 34002-0948, USA; [5]Departamento de Histología, Facultad de Medicina, Universidad de Panamá, Panamá, Rep. de Panamá (e-mail: IBANEZR@si.edu).

LAMPROPELTIS ALTERNA (Gray-banded Kingsnake). MEXICO: DURANGO: Municipio de Santiago Papasquiaro: East slope of the Sierra Madre Occidental (25.087°N, 105.542°W, WGS 84), 2218 m elev. 31 July 2007. J. Reyes Velasco and M. J. Ingrasci. Verified by J. A. Campbell. University of Texas Arlington Digital Collection (UTADC 1096). New municipality

record, third record for Durango, and first record for Sierra Madre Occidental, extending the known range ca. 100 km W of the closest other known Durango record, 5 mi. S of San Antonio near El Banco; 26 mi. N San Juan del Río, 4700 ft. elev. (Tanzer 1970. Herpetologica 26:419–428 [as *L. mexicana*]). Garstka (1982. Breviora 466:1–35 [as *L. alterna*]) reported the same specimen using the 26 mi. N San Juan Del Río locality (TCWC 36892) and Gadsden et al. (2006. Bull. Chicago Herpetol. Soc. 41:2–9) reported another taken in the Sierra el Sarnoso, Municipio Lerdo (between 1100 m and 1350 m elev.) in the northeastern portion of the state. The other two records are from Chihuahuan Desert scrub vegetation, whereas the snake reported herein was found in Madrean woodland vegetation at a higher elevation.

MICRURUS SURINAMENSIS (Surinam Coralsnake). BRAZIL: GOIÁS: Municipality of Aragarças, confluence of Caiapó River with Araguaia River (15.9042ºS, 51.845ºW; datum SAD69 or 0409536, 8241455; 310 m elev.). 07 December 2007. I. Jr. Tonial. Museu de Zoologia da Universidade de São Paulo, São Paulo, Brazil (MZUSP 17211, juvenile male, 265 mm SVL). Verified by H. Zaher. The species is known from a wide range west of Araguaia River and north reaching Mato Grosso, Eastern Pará, Amapá, and Roraima states in Brazil; also known from Guyana, Suriname, French Guiana, and southern Venezuela (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. 2 vols. Cornell University Press. Ithaca, New York. 774 pp.; Strüssmann and Carvalho 1998. Herpetol. Rev. 29:183–185). This is the southeastern most and first state record (state of Goiás) for *M. surinamensis*, extending the known distribution ca. 594 km SSE of Nova Olímpia (14.7833ºS, 57.2833°W; datum SAD69; Mato Grosso), the only locality officially recorded for this species in southern Mato Grosso to date (Strüssmann and Carvalho, *op. cit*.).

Submitted by **NELSON JORGE DA SILVA JR**, **HÉLDER LÚCIO RODRIGUES SILVA**, Departamento de Biologia, Universidade Católica de Goiás, Ave. Universitária, 1440, Setor Universitário, 74.605-010, Goiânia, Goiás, Brazil; and **ANITA DE MOURA PESSOA**, Systema Naturae Consultoria Ambiental Ltda, Rua 58, nº 217 – Jardim Goiás, 74.810-230, Goiânia, Goiás, Brazil (e-mail: herp@terra.com.br).

NERODIA FASCIATA CONFLUENS (Broad Banded Watersnake). USA: TEXAS: Marion Co.: On the edge of a cattle pasture (Cypress River Ranch, FM 2208) and bottomland hardwood forest adjacent (ca. 100 m) to Big Cypress Bayou (32.7516306ºN, 94.3773056ºW) near Jefferson, Texas. 7 February 2006. Thomas Rainwater. Verified by C. Bob Sanders. Campbell Museum (CUSC 2363), Clemson University, Clemson, South Carolina. County record. Freshly dead from apparent head injury. Fills distributional gap of species in northeast Texas (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed. Texas A&M University Press, College Station, Texas. 421 pp).

Submitted by **THOMAS R.RAINWATER**, The Institute of Environmental and Human Health, Texas Tech University, P.O. Box 764, Jefferson, Texas 75657, USA (e-mail: trrainwater@gmail.com); **STEVEN G. OXYRHOPUS RHOMBIFER RHOMBIFER (Coral-falsa). BRAZIL: BAHIA. Municipality of Paulo Afonso (9.4ºS, 38.2ºW). May 1988. Collectors unknown. Coleção Científica de Serpentes do Museu de Zoologia da Universidade Federal da Bahia, Salvador, Bahia, Brazil (UFBA 182, 187, 196, 199, 214). Verified by F. L. Franco. Species previously known from "província de Buenos Aires to east of Rio Paraná in Argentina," Uruguay, and in the Brazilian states of Rio Grande do Sul, Santa Catarina, Paraná, Minas Gerais, São Paulo, Rio de Janeiro, and

Bahia (Argôlo and Freitas 2000. Herpetol. Rev. 31:55; Peters and Orejas-Miranda 1970. Bull. U.S. Nat. Mus. 297:235). Second record of the species from northeastern Brazil, extends range ca. 350 km N from Lençóis, the previous northernmost locality (Argôlo and Freitas 2000, *op. cit.*).

Submitted by **BRENO HAMDAN (**e-mail: brenohamdan@gmail.com), and **REJÂNE MARIA LIRA-DA-SILVA**, Núcleo Regional de Ofiologia e Animais Peçonhentos da Universidade Federal da Bahia, Rua Barão de Geremoabo, 147 - Campus de Ondina, CEP 40170-290, Salvador, Bahia, Brazil.

PARIAS SUMATRANUS (Sumatran Pit Viper). BRUNEI DARUSSALAM: Ulu Temburong National Park: nr. Sungai Sibut. 01 October 2006. Alexander Keller, Matthias Siegle, and T. Ulmar Grafe. Photo voucher, Staatliches Museum für Naturkunde Stuttgart, SMNS V-1-001. Verified by Indraneil Das. Encountered coiled up within a rattan palm. On approach, showed aggressive behavior (hissing and directed extension). After several minutes of observation, disappeared into canopy of nearby tree. Length (ca. 1 m) and reddish tail suggest it was a juvenile.

Submitted by **ALEXANDER KELLER**, University of Würzburg, Department of Animal Ecology and Tropical Biology, Biocenter, Am Hubland, 97074 Würzburg, Germany; e-mail: info@biotopia.info.

PSEUDOLEPTODEIRA LATIFASCIATA (False Cat-eyed Snake). MEXICO: OAXACA: Municipality of Santiago Tamazola: road from Santiago Tamazola to Santa Rosa (17.4400°N, 97.5026°W, estimated from map), 1230 m elev. 15 July 2003. Verified by Edmundo Pérez Ramos. Museo de Zoología, Facultad de Ciencias, UNAM (MZFC 17890). First record from Oaxaca, extending its known range 58 km S of the nearest locality at Piaxtla, Puebla (Duellman 1958. Bull. Amer. Mus. Nat. Hist. 114:1–152). The specimen was found dead in oak forest.

Submitted by **LUIS CANSECO-MÁRQUEZ (**e-mail: lcanseco@gmail.com), and **ANA LAURA NOLASCO VÉLEZ,** Departamento de Biología Evolutiva, Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autónoma de México, A.P. 70-399, C. P. 04510, México, D. F., México.

RAMPHOTYPHLOPS BRAMINUS (Brahminy Blindsnake). MÉXICO: TABASCO: Municipality of Centro, Municipality Palace of Villahermosa (17.5944°N, 92.5644°W, WGS 84), 10 m elev. 14 July 2007. José G. Paz Gutiérrez. Verified by Ireri Suazo Ortuño. Colección Herpetológica del Instituto de Investigaciones sobre los Recursos Naturales, Universidad Michoacana de San Nicolás de Hidalgo (INIRENA 678). First record for Tabasco and a 345 km SE (airline) range extension from Playa Mocambo, Veracruz (Mendoza-Quijano et al. 1993. Herpetol. Rev. 24:110) and 352 km NE (airline) from Cuicatlán, Oaxaca (Mendoza Quijano et al. 1994. Herpetol. Rev. 25:34). These records suggest that this exotic species is well established on the Gulf lowlands of México in a similar fashion as on the lowlands of the Pacific versant (Mata-Silva et al. 2007. Herpetol. Rev. 38:356)

Submitted by **JOSÉ GIL PAZ GUTIÉRREZ**, **CARLOS SOTO ROJAS,** and **JAVIER ALVARADO DÍAZ**, Laboratorio de Herpetología, Instituto de Investigaciones sobre los Recursos Naturales, Universidad Michoacana de San Nicolás de Hidalgo, Av. San Juanito Itzicuaro s/n, Morelia, Michoacán, México 58330 (e-mail: kumo345@hotmail.com).

REGINA GRAHAMII (Graham's Crayfish Snake). USA: ILLINOIS: Macon Co.: Decatur Lake at Reas Bridge Rd (39.88255ºN, 88.86804ºW). 19 May 2007. Collected by Leroy J. Walston Sr. Verified by C. A. Phillips. Illinois Natural History Survey, University of Illinois. Color photograph voucher (INHS 2008.12). One subadult (40 cm TL) captured along shoreline among rocks. First county record, filling the gap among central Illinois counties (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Manual 8, Champaign, Illinois, 282 pp.).

Submitted by **LEROY J. WALSTON SR**., 1835 N. Bender Rd., Decatur, Illinois, 62521, USA; and **LEROY J. WALSTON JR**., Argonne National Laboratory, 9700 S. Cass Ave., Argonne, Illinois, 60439, USA (e-mail: lwalston@anl.gov).

SALVADORA GRAHAMIAE LINEATA (Texas Patch-nosed Snake). USA:TEXAS: Shackleford Co.: Hwy 351 ca. 4.8 km S of jct. with Hwy180 (32.6239167ºN; 99.4716333ºW). Collected by Edwin L. Gainey. Verified by Carl Franklin. University of Texas at Arlington Ampibian and Reptile Biodiversity Research Center (UTA R-55847). New county record. (Dixon 2000. Amphibians and Reptiles of Texas. Second ed. Texas A&M University Press, College Station, Texas. viii+421 pp; Dixon et al. 2007. Texas Herpetol. Soc. Publ. 2007:1–58).

Submitted by **CHRISTIAN L. COX (**e-mail: clcox@uta.edu), **COREY E ROELKE,** University of Texas at Arlington, Department of Biology, 501 S. Nedderman Dr., Arlington, Texas 76019, USA; and **BRANDON POPE,** 1706 Nueces Trl Arlington, Texas 76012, USA.

SIBON LAMARI (Caracolera). PANAMÁ: BOCAS DEL TORO: Distrito de Changuinola: Río Changuinola, El Guayabal (9.2104°N, 82.4699°W; WGS84), 150 m elev. 13 June 2007. Jhoana De Alba and César A. Jaramillo. Círculo Herpetológico de Panamá (CH 6214). COLÓN: Distrito de Donoso: La Sargenta, Río Toabré (8.9314°N, 80.5144°W; WGS84), 60 m elev. 22 March 2002. Roberto Ibáñez D. Círculo Herpetológico de Panamá (CH 5402). Punta Rincón (9.0210°N, 80.6862°W; WGS84), 5 m elev. 08 January 1983. Fidel E. Jaramillo A. Museo de Vertebrados de la Universidad de Panamá (MVUP 1892). All specimens verified by Alejandro Solórzano. New records for Panamá, extending the geographic range ca. 355 km (airline) SE of the nearest locality in Costa Rica and elevational range from 650 m to the lowlands (Solórzano 2004. Serpientes de Costa Rica: Distribución, Taxonomía e Historia Natural. Instituto Nacional de Biodiversidad, Santo Domingo de Heredia, Costa Rica. 791 pp.).

Submitted by **CÉSAR A. JARAMILLO A.**[1,2,3], **ROBERTO IBÁÑEZ D.**[1,2,4] **FIDEL JARAMILLO A.**[1,5], and **FRANK A. SOLÍS**[1,4]. [1]Círculo Herpetológico de Panamá, Apartado 0824-00122, Panamá, Rep. de Panamá; [2]Smithsonian Tropical Research Institute, Unit 0948, APO AA 34002-0948, USA; [3]Departamento de Histología, Facultad de Medicina, Universidad de Panamá, Panamá, Rep. de Panamá; [4]Departamento de

STORERIA O. OCCIPITOMACULATA (Northern Red-bellied Snake). USA: MARYLAND: DORCHESTER CO.: 2.5 km NE of Blackwater near Barnes Landing on Blackwater Rd. (38.4166ºN, 76.125ºW). DOR adult, 05 November 1994. Arthur and Zack Meilhammer. Verified by Ned S. Gilmore, Academy of Natural Sciences, Philadelphia (ANSP 36239). New county record, verifies county record on distribution map in White and White (2002. Amphibians and Reptiles of Delmarva. Tidewater Publishers, Centreville, Maryland. 248 pp.).

Submitted by **WILLIAM L. GROGAN, JR**., Department of Biological Sciences, Salisbury, Maryland 21801, USA; e-mail: wlgrogan@salisbury.edu.

XENODERMUS JAVANICUS (Rough-backed Litter Snake). BRUNEI DARUSSALAM: Ulu Temburong National Park: nr. Sungai Esu. 22 September 2006. Alexander Keller, Matthias Siegle, and T. Ulmar Grafe. Photo voucher, Staatliches Museum für Naturkunde Stuttgart, SMNS V-2-001. Verified by Indraneil Das. Encountered three times (August–September 2006) within riparian areas with leaf litter. Nearby streams were small, < 5 m wide, and not deeper than 50 cm. In all cases, in hilly terrain with moderate vegetation. Encounters were > 1 km apart from each other, for which reason it is assumed the snakes were different individuals.

Submitted by **ALEXANDER KELLER**, University of Würzburg, Department of Animal Ecology and Tropical Biology, Biocenter, Am Hubland, 97074 Würzburg, Germany; e-mail: info@biotopia.info.

e-mail: martin.jansen@gmx.net

The last comprehensive list of Bolivian snakes with information about their distribution was published by Fugler et al. (1995). Since then, several new species, new country records and revisions have been published (e.g., Harvey 1994; 1999; Harvey et al. 2003; 2005; Reichle and Embert 2005; Embert et al. 2006; Jansen 2006). The present note provides three new country records, four new departmental records and other noteworthy records of snakes in Bolivia. The fieldwork was done during November 2004 and April 2005 and October 2005 and March 2006 predominantly in the eastern lowlands of Bolivia. The specimens were deposited in the Museo Noel Kempff Mercado (MNKR), Santa Cruz, and Museum Senckenberg (SMF), Frankfurt. The identities of the specimens were verified by G. Köhler (except *Thamnodynastes chaquensis* verified by F. L. Franco).

Clelia bicolor. BOLIVIA: SANTA CRUZ: Hacienda El Espinal, Pantanal, San Matias (17.0372167ºS, 58.5305667°W; 124 m). 15 April 2004 and 23 January 2005. Martin Jansen. SMF 86639, MNKR 4255. First record for Bolivia. *Clelia bicolor* occurs in southern Mato Grosso, Brazil, south to Paraguay and northern Argentina, and inhabits lowlands of the Platine Plains, Chaco, Pantanal, and their boundaries (Franco et al. 1997; Zaher 1996). The next known locality is ca. 210 km SE, in the Pantanal at Poconé, Mato Grosso, Brazil (Strüssmann and Sazima 1993).

Lystrophis pulcher (South American Hognose Snake). BOLIVIA: TARIJA: Villa Montes. 1 May 1927. F. Berg. SMF 32470. First departmental record. The species occurs in the Chacoan region of Argentina (Jujuy, Salta, Catamarca, Tucumán, Santiago del Estero, Formosa, Chaco, Córdoba, San Luis, Entre Dios, and Corrientes provinces), south of Paraguay and was known for Bolivia only from San Ignacio de Velazco, Department of Santa Cruz (Scrocchi and Cruz 1993). Nearest known locality is in Salta, Argentina, ca. 100 km S.

Lystrophis mattogrossenis (South American Hognose Snake). BOLIVIA: SANTA CRUZ: Provincia Ñuflo de Chavez, Hacienda and RPPN San Sebastián (16.3624833ºS, 62.02195ºW, 537 m). 08 November 2005. Martin Jansen and Arne Schulze. MNKR 4257. Second record for Bolivia. The species was only known from Mato Grosso and Mato Grosso do Sul states, Brazil to lowlands of eastern Bolivia (Giraudo 1997; Scrocchi and Cruz 1993). Extends the range about 350 km W from westernmost known locality in Sandoval, Department of Santa Cruz, Bolivia (Giraudo 1997).

Micrurus frontalis (Cerrado Coral Snake). BOLIVIA: SANTA CRUZ: Provincia Ñuflo de Chavez, Hacienda and RPPN San Sebastián. 29 November 2005 and 28 December 2005. Martin Jansen and Arne Schulze. MNKR 4253, SMF 86637. First country record. The species was only known from the Cerrado formations of Central Brazil (including Sao Paulo and Minas Gerais) west to the border of Bolivia and the Brazilian states of Mato Grosso and Mato Grosso do Sul. Extends the range at least 400 km W from westernmost known locality in Mato Grosso (Campbell and Lamar 2004; Silva and Sites 1999). Harvey et al. (2003) suspected *M. frontalis* to occur in Bolivia.

Phalotris nasutus. BOLIVIA: SANTA CRUZ: Provincia Ñuflo de Chavez, Hacienda and RPPN San Sebastián (16.3877167ºS, 61.9997167ºW; 566 m). 26 October 2005. Martin Jansen and Arne Schulze. MNKR 4256. First country record. *Phalotris nasutus* was only known from the Cerrados in central Brazil to north and southwest (Lema 2002). Enlarges the range of *P. nasutus* substantially to the west. The nearest known locality in Mato Grosso lies ca. 850 km E (Lema 1999).

Thamnodynastes chaquensis. BOLIVIA: SANTA CRUZ: Hacienda and RPPN El Espinal, Pantanal, San Matias. 17 April 2005 and 24 January 2006. Martin Jansen. MNKR 4284 (17.04ºS, 58.5189667ºW, 99 m), SMF 86332 (17.0372167ºS, 58.5305667ºW; 124 m). Verified by F. L. Franco from photographs and data of squamation. First departmental record. This species is

distributed from Paraguay, Uruguay, northeastern Argentina, and Brazil (Carreira 2003; Giraudo 1996; Giraudo and Scrocchi 2002; Franco and Ferreira 2002; Leynaud and Bucher 1999). In Bolivia it was only known from Tariquía, Department of Tarija (Lavilla and Scrocchi 1999). The nearest known locality is ca. 210 km SE, in the Pantanal at Poconé, Mato Grosso, Brazil [a photograph of *Thamnodynastes* sp. by Strüssmann and Sazima (1993) shows *T. chaquensis* according to Franco and Ferreira (2002)].

Xenodon rhabdocephalus. BOLIVIA: SANTA CRUZ: Hoyada (Prov. Florida, north of Aguaclara, at the southern limits of the Parque Nacional Amboro, 1650–1900 m) and RPPN Los Volcanes (18.1059ºS, 63.5977667ºW; 1051 m). 15 October 2004 and 09 March 2005. Eduardo Mamani, Fray Andres Langer and Martin Jansen. First departamental record. In its large distributional area from Central America and South America south to Brazil and Bolivia (Paolillo 1984) the species was only known from sea level to about 1300 m (Wilson and Meyer 1982). The record from the locality Hoyada extends the vertical distribution from *X. rhabdocephalus* at least 300 m. The record from Los Volcanes extends the distribution at least 350 km SSE; the nearest known locality is at the Rio Mamoré, Beni, Bolivia (Fugler et al. 1995).

Acknowledgments.—I thank the Los Volcanes (A. Schwiening) and San Sebastian (L. Werding) for their invitation to conduct research on their properties. I am grateful to the Dominican Monk Fray Andres Langer, Pampagrande, who provided help whenever and however he could. I thank A. Schulze for invaluable field assistance, and also the co-workers of the haciendas. Collecting and exportation permits were provided by the Ministerio de Desarrollo Sostenible, La Paz, and Servicio Nacional de Sanidad Agropecuaria e Inocuidad Alimentaria (SENASAG). P. Herrera and A. Justiniano, Museo Noel Kempff Mercado, Santa Cruz, provided valuable assistance with acquisition of these permits. I thank G. Köhler and F. L. Franco for verifying species identifications. G. Köhler provided many useful comments on the manuscript. Fieldwork in Bolivia was funded by a grant from the German Academic Exchange Service (DAAD).

In the Preface to *Biology of Turtles* (BOT) the authors explain that their book is the result of a turtle anatomy symposium at the Sixth International Congress of Vertebrate Morphology held at Jena, Germany in 2001. Given the morphological focus of the conference, the book's purview encompasses several fields of biology within an anatomical context, including developmental biology, functional morphology, behavior, physiology, evolution and systematics. Thirty-five contributors from the United States and Europe provided 13 chapters that are discussed in detail below.

The first chapter (16 pages) by Scott Gilbert and colleagues explains the detailed process of ossification of the shell in turtles. The authors discuss how heterotopy and paracrine factors affect formation of the carapacial bones in the well-studied genera *Trachemys*, *Chelydra* and *Pelodiscus*. These same genera are the focus of the authors' discussion of neural crest cells and heterochrony during plastron formation. A final, brief section summarizes the evolutionary implications of shell formation, including a discussion of the anapsid-diapsid debate, and how different kinds of data have been used to reach different conclusions about the origin and classification of turtles.

Chapter 2 (27 pages) by Melissa Snover and Anders Rhodin focuses on the application of skeletochronology (specifically LAG's, or lines of arrested growth) to estimate age and growth rates in turtles. The two patterns of bone growth in turtles are discussed in detail in the next section, but the authors focus on chondro-osseous development in the leatherback sea turtle *Dermochelys coriacea*, which is unique among turtles—this fascinating section is richly illustrated with detailed photographs of fresh bone preparations, histological cross sections of bone, and electron micrographs of extant sea turtles, as well as joint surfaces of several extinct sea turtle genera. The evolution of vascularized cartilage in the superfamily Dermochelyidae is explored in the context of three competing hypotheses of phylogenetic relationships. Finally, the authors explain how their results demonstrate that *Dermochelys* is unique among turtles in relation to rates of growth to sexual maturity.

Peter Pritchard is the author of Chapter 3 (39 pages), which discusses the origin of turtles within the context of fossils and morphology, and then explores variation in turtle shells (including osteology, scutes and kinesis) in detail. Additional sections discuss sexual dimorphism, ankylosis, fontanels, plastral reduction, deformities (including "pyramiding," kyphosis, scute abnormalities, and premature ankylosis of individual shell sutures), and geodesics. Finally, specialized and unusual shell morphologies are discussed in the families Cheloniidae, Dermochelyidae, and Trionychidae. This chapter includes 38 black-and-white photographs of shell variation in turtles.

The brief Chapter 4 (12 pages) by Gustavo Llorente and colleagues is entitled "Long Bone Allometry in Tortoises and Turtles." The authors compare limb bone diameters and lengths across 11 families of turtles to test whether "limb scaling" differs among terrestrial and aquatic chelonians (possibly as a result of locomotor adaptations), and follows patterns described previously in other tetrapods. Their results are consistent with a "geometrical similarity" hypothesis, and it seems that turtle bones are more similar to the shape of bird bones than the long bones of quadrupedal mammals. Future directions to investigate the role of locomotor adaptation on the appendicular shape of turtles are discussed.

Sabine Renous and colleagues examine the relationship among morphological variation of extant and extinct turtle locomotor systems, their function, and diversity of aquatic and terrestrial habitats in Chapter 5 (42 pages). The chapter includes a discussion of environmental constraints and the origin of aquatic turtles, structural constraints on the chelonian body plan, and a detailed analysis of morphological variation in aquatic environments. The topic transitions to a section about locomotion in aquatic turtles, including different functions of the limb, propulsion, kinematics, and limb coordination.

Chapter 6 (24 pages) by Richard Blob and colleagues is entitled "Hindlimb Function in Turtle Locomotion: Limb Movements and Muscular Activation across Taxa, Environment, and Ontogeny." The authors compare aquatic and terrestrial patterns of hind limb kinematics and muscle activation (EMG) between aquatic, highly specialized spiny softshell turtles (*Apalone spinifera*) and generalized, semiaquatic sliders (*Trachemys scripta*). One section of the chapter compares adults of the two species, and although both species have largely similar modulation patterns, several interesting contrasts in hind limb function are discussed. A similar investigation of *Apalone* and *Trachemys* juveniles notes that several of the interspecific differences of adults are not evident in juveniles. The chapter ends by discussing future directions for studies of turtle locomotion.

The aim of Anthony Herrel and colleagues in Chapter 7 (23 pages) is to provide a detailed description of the cervical sys-

tem in pleurodiran (horizontal plane head retraction) and cryptodiran (vertical plane head retraction) turtles, and to emphasize the functional consequences of differences in morphology in the two groups. The authors studied the preserved anatomy of *Chelodina longicollis*, *C. reimani*, *Apalone ferox*, and *A. spinifera*, and used live animals from each species to study the kinematics of snorkelling behavior. The cervical vertebrae and musculature are illustrated in detail for *C. longicollis* and *A. spinifera*. Differences in these structures and movement patterns are discussed for both groups.

Chapter 8 (26 pages) by Vincent Bels and colleagues provides the first comparative analysis of feeding behavior in turtles, especially in marine and terrestrial species. An overview of turtle feeding and drinking behaviors is provided, and then the chapter focuses on the kinematics of terrestrial ingestion, the intra-oral transport cycle, swallowing, aquatic ingestion, and a specific case of feeding in *Dermochelys coriacea*. The chapter is illustrated with several schematic feeding diagrams, frames of video of feeding behavior, x-ray videofluoroscopy, and high-speed x-ray film sequences.

A brief Chapter 9 (12 pages) by BOT's lead editor Jeanette Wyneken explores the anatomy of the circulatory and pulmonary systems in turtles, including sections on the heart, great vessels and major tributaries, lungs and airways, cardiopulmonary circulation, ventilation, cardiovascular shunts, and respiratory physiology. Differences in these structures among turtles are generally correlated with ecology and behavior. The chapter ends with a comparison of turtle cardiopulmonary structures to other reptiles.

BOT's longest chapter (54 pages), by Jeffrey Miller and Stephen Dinkelacker, is a literature review entitled "Reproductive Structures and Strategies of Turtles." The authors state that their focus is on the morphological diversity of chelonian reproductive structures and the effects these have on the range of reproductive strategies exhibited by turtles; an extensive references section (18 pages) is provided to stimulate further research. The authors discuss variation in reproductive structures in several sections including general morphology, gonads, the oviduct, cloaca and associated structures, hormonal changes during reproduction, and eggs. A second, ambitious section on reproductive strategies explores sexual dimorphism, mating behavior, seasonal timing of reproduction, insemination and sperm storage, fecundity (including shape and number of eggs and clutches), nesting patterns and density, ovipositional site selection and oviposition, embryonic development and incubation, sex determination, developmental arrest, hatching and hatchling survivorship, overwintering, and growth. The authors have synthesized an ambitious amount of information in this chapter, and although the authors state that their literature review is not meant to be comprehensive, I would be remiss if I didn't point out that they omitted *Apalone spinifera* from the list of trionychid developmental stage studies (Greenbaum and Carr 2002). In the review of turtle development, it would have been nice to include several recent, detailed turtle development studies by Christopher Sheil that provide incubation data that are relevant to the discussion (e.g., Sheil 2003, 2005).

Chapter 11 (22 pages) by Vincent Hulin and colleagues is entitled, "Mixed and Uniform Brood Sex Ratio Strategy in Turtles: The Facts, the Theory, and Their Consequences." The authors have three goals in this chapter: (1) theoretically compare strategies producing unisex or mixed-sex ratios within a nest and their contribution to the population; (2) assess the risk of extinction of turtle populations according to the brood sex ratio strategy (mixed or unisex nests) used by individuals; and (3) compare their theoretical predictions with real-world scenarios from the literature. The authors discuss these aspects in detail and explain how they are related to the evolution of temperature-dependent sex determination (TSD) and its consequences to turtle evolution. One interesting section discusses global warming and the fate of TSD turtles, exploring different adaptive strategies that turtles might use to survive into the 22nd century. This chapter seems somewhat out of place with the rest of the contributions in BOT because it does not have an anatomical focus.

Sarah Milton is the author of Chapter 12 (44 pages) entitled, "The Physiology and Anatomy of Anoxia Tolerance in the Freshwater Turtle Brain." The chapter begins with an introduction to the central nervous system and brain, and continues with sections on "the brain in crisis," the anatomy and physiology of anoxic survival, energy supply and the enzymes of anaerobic glycolysis, ion channels, neurotransmitters and neuromodulators, excitatory neurotransmitters, nitric oxide, the visual system, antioxidants, and neurogenesis. The chapter concludes by saying that anoxia-tolerant turtles do not differ significantly from mammals and most other vertebrates in brain structure, neuronal pathways or presence/absence of specific neurotransmitters, but rather in the expression of protective pathways that are expressed more robustly and successfully in turtles.

BOT's shortest and last Chapter 13 by Olivier Rieppel (9 pages) begins with a discussion of the unique morphology of turtles, a lack of intermediate fossils, and the resulting difficulty with comparisons to other reptiles. Subsequent sections briefly discuss the history of changing ideas regarding turtle origins and relationships, the current status of the debate, and the ecological setting of turtle origins. Rieppel notes a general consensus has emerged that places turtles among the diapsid reptiles, but it is not yet clear whether they are more closely related to the lepidosauromorph or archosauromorph clades. A recent study of tetrapod RAG-1 sequences by Hugall et al. (2007) supports the latter choice, but the controversy is certain to continue for the foreseeable future.

In general, the quality of writing and illustrations in BOT are good, but I did note a few minor issues: pg. 1, "hardback turtles of the Emys [sic] and Chelydae families" instead of Emydidae and Chelydridae; pg. 2, "suprepygeal" instead of suprapygal; pg. 47, "…spines on the long tail, not the mention the ones on the back…"; pg. 165, "*A. spiniferus*" instead of *A. spinifera*; pg. 201, "*Trachymys*" instead of *Trachemys*; pg. 345, omitted parenthesis. The formatting of the References for each chapter was not consistent, and I noticed problems with switching the position of volume and publication years, and inconsistencies in how page ranges are provided. There also seem to be problems with consistent taxonomy among the chapters, especially with higher taxa—Chapter 1 (pg. 1) refers to turtles as Chelonia instead of Testudines as used in Chapter 13; Chapter 8 (pg. 201) lists *Cuora* in the Family Emydidae, but it should be in the Family Geoemydidae. It would have been helpful to include generalized diagrams of the carapace and plastron to guide the novice through scute terminology, especially because two chapters are devoted to shell morphology

and development. The price of US $150 seems expensive given the lack of color plates in most of the chapters, but the binding is sturdy and the book is printed on acid-free paper. These concerns aside, BOT is a useful reference for anyone interested in the morphology and evolution of turtles.

Acknowledgments.—John L. Carr provided comments on an earlier version of the manuscript.

Adenauerallee 160, D-53113 Bonn, Germany
e-mail: w.boehme.zfmk@uni-bonn.de

On the occasion of the 50th anniversary meeting of the SSAR in Saint Louis, Kraig Adler brought out the second volume of his important work *Contributions to the History of Herpetology*. This second volume, being conspicuously more lengthy than the first (Adler 1989), again contains as its main part the biographies of "Herpetologists of the Past" sorted by time spans associated with the years of publication of their first herpetological work. These time intervals start with centuries (1400–1700), followed by one period of eight decades (1700–1780), then two periods of two-decades (1780–1820), followed by ten single decades (1820–1920), then shifting to six pentades from 1920–1950. After that, two decades follow (1950–1970) and finally a span of 20 years (1970–1990) concludes this section. The varying length of these periods reflects (1) that only few early herpetologists (or, more accurately, naturalists who have published on amphibians and reptiles) were not already treated by Adler (1989), and (2) that a large number of herpetologists who lived in the 19th and 20th centuries merited inclusion in this work. The shift to decade and two-decade periods at the end, in contrast, rather reflects the fact that many herpetologists who started publishing after 1950, and especially those beginning publishing from 1960 or 1970 onwards, are largely still alive and, therefore, have to "wait" to be included in Volume 3!

In the present volume the author was able to add no less than 285 new biographies to those contained in Volume 1. They range from Leoniceno in the 16th century, over nearly five centuries, to Joseph Slowinski who died only a few years ago (2001) in a tragic snake bite event. Not only was Adler successful in searching for biographic data and obituaries for all these predecessors and former colleagues of our discipline, but he also was able to collect portraits and signatures for nearly every one of them.

Considering the huge number of biographies, I approach this book as a curious, learning reader, and only in a few cases, can I provide a few additional details that might be useful, especially should the two volumes be fused into one new edition in the not-too-distant future (Volume 1 is now out of print). Of course, due to my personal experience, my few comments refer mainly to German herpetologists and institutions, but certainly this book will also be reviewed in many other journals from countries that also produced prominent herpetologists featured in this volume, so that other reviewers will direct their focus on persons relevant to their respective experiences.

The first point I should like to mention is the "Note" which follows the accounts on Johann Friedrich Blumenbach (p.31), Adolph Arnold Berthold (p. 69) and Wilhelm Keferstein (p. 87), three persons closely connected with the Zoological Museum of the University Göttingen which is, by the way, the oldest institutional natural history museum in Germany (at that time Kingdom of Hannover, now federal state of Lower Saxony). The note after their biographies identically states: "In 1977 the entire Göttingen collection was transferred to the Museum Alexander Koenig in Bonn." However, this is true only for the alcoholic collection of amphibians, reptiles and mammals (Böhme and Bischoff 1984; Hutterer 1984). For instance, the fish collection went to the Zoological Museum of the Hamburg University, the crustaceans were given to the Senckenberg Museum in Frankfurt am Main (Türkay, 1988), and the ornithological collection (the so-called Kirchhoff collection: ca. 4000 mounted birds, including extinct species) went to the Niedersächsisches Landesmuseum in Hannover. Dry, mounted mammal and reptile specimens stayed in Göttingen, where only a small teaching collection and a collection for public display was retained.

In the case of Heinrich Rudolf Schinz (p. 51) it would be worth mentioning his long term scientific correspondence with Prinz Maximilian zu Wied-Neuwied (Vol. 1, p. 22). Schinz loaned books to Wied who prepared handwritten copies, e.g., of the fish part of von Siebold's *Fauna Japonica*. In the latter case he even prepared more than 70 color plates, all personally redrawn from Schinz's copy of this book, in order to save some 120 Thaler. This

work is still in existence in the familial archives of Neuwied Castle (near Koblenz, Germany). This interesting correspondence took place – with longer intervals – between 1821 and 1854 and is housed in the University Library of Zürich, Switzerland.

The paragraph on Franz Leydig (p. 77) stresses the merits of this important anatomist in not only having created the term "Feinstruktur" but actually having discovered the fine structure of many glandular and sensory organs of amphibians and reptiles. I think it would be also worth while to mention here his discovery and first description (Leydig 1857, 1872) of the microscopic "stachliges" (= spiny) epithelium on the hemipenial surface in two lacertid lizard species, as this particular structure was subsequently found to be taxonomically relevant for lacertid systematics (Böhme 1971; Arnold 1973).

Gustav Tornier (p. 127) left us with a number of scientific herpetological names (e.g., *Lacerta vauereselli* – now *Adolfus vauereselli*, *Chamaeleon jacksoni* var. *vauerescecae* – now *C. j. jacksonii*), and *Geodipsas vauerocegae* – now *Buhoma vauerocegae*), the etymological derivation of which seems really improbable for those who have not heard the story. Fortunately, I learned it from one of Tornier's successors in Berlin, Günther Peters. Tornier felt that it might be advantageous if a species name included information on the position of the respective species in the zoological system. So he developed a naming system based on the initial letters of the higher categories the species belonged to. Thus, *L. vauereselli* was derived from the initial letters V for Vertebrata, R for Reptilia, S for Sauria, and L for Lacertidae, giving in (German) spoken form Vau, Er, Es, El, supplied with the masculine genitive singular ending *-li*. Accordingly, *C. vauerescecae* refers to a vertebrate reptilian saurian of the family Chamaeleonidae (VRSC), here supplied with the feminine genitive singular ending *-cae*. *Buhoma vauerocegae*, accordingly, is a vertebrate reptilian ophidian colubrid (VROC), here equipped with the feminine genitive singular ending *-gae*. I think it would be a pity if knowledge of Tornier's strange method of name construction were to be lost.

A small correction is necessary in respect to the account on Heinz Wermuth (p. 216). He did not, as stated in this account, "initiate," together with the paleoherpetologist and mammalogist Wolf Herre, the series *Handbuch der Reptilien and Amphibien Europas* which then was edited by myself from 1981 onwards. The first initiative was made by the publisher who approached me in order to complement multi-volume series on the birds of Central Europe and the mammals of Europe, which had begun in 1979. Rather, both Wermuth and my former doctoral supervisor Herre each agreed, at my request, to write a preface each for the first volume of this series.

Similar slight amendments, minor additions, and cross-references could certainly be made on some other herpetologists forming part of this volume but their accounts will have to be evaluated by readers of their respective nationalities. Any such comments aside, however, Kraig Adler, is to be admired for the massive task of again compiling such a huge amount of herpetobiographical information.

Apart from the main part of the book discussed above, Kraig Adler again engaged Richard Applegarth and Ronald Altig for the two following chapters of the book. Applegarth compiled a second edition of his Index of Authors in Taxonomic Herpetology which is an impressive list of nearly 60 pages with about 60 names per page on average. Here, in contrast to the first part, recent authors also figure alphabetically amongst their deceased predecessors and colleagues. Despite the large number of names with their dates of birth and death, there are some persons where the dates of birth are replaced by a question mark. Among them are even persons mentioned in the acknowledgements at the beginning of the book, so that the search for at least some of these dates should have been rather easy. But again, so few omissions within so many data really seem a "quantité négligeable" to me.

The same is true for the final part of the book, the second edition of the Academic Lineages of Doctoral Degrees in Herpetology compiled by Ronald Altig. The lineages are arranged by country in alphabetical order, starting with Armenia and ending with Zimbabwe. Although several of these countries do not have their own lineages, they are nonetheless listed and readers are referred to other countries in which relevant herpetologists were trained academically. The information given concerns the year of the doctoral award and the university where it was achieved. Again, some question marks could have been easily replaced by hard data — one e-mail would have been enough in some cases! But here it is also true that the vast majority is complete so that the few omissions are insubstantial. Turkey is listed but only with the hint "see Germany." Although it is correct that Muhtar Başoğlu was a doctoral student of Kurt Cosswig in Hamburg, the lineage founded by him at the Aegean University in Bornova-Izmir is so important and independent, not to mention the numerous academic "F2 generation" produced in Izmir, that it certainly merits listing under a Turkish, rather than German, signet.

In the German lineages, I found some errors and omissions including my own one which could easily be corrected or supplemented in a future edition: A nice, important starting point for a first series in Germany would have been the famous J.F. Blumenbach, with his likewise important academic offspring Adolph Arnold Berthold and Prince Maximilian zu Wied-Neuwied. Series 2: 001. The doctoral supervisor of Wolf Herre was Bruno Klatt. 003. My own former doctoral students S. Etti, J. Handwerk, K. Schmidt-Loske, and A. Schunke worked with topics other than herpetology, and Ronald Altig obviously got my list from someone else. Series 4: 004. Heinz Wermuth, student of Martin Eisentraut, did not establish his own university-related working group. Rather he co-supervised theses in cooperation with university professors; for example, that on New Guinean crocodiles by Dietrich Jelden. Günther Peters, however, who is listed here as his student, was in fact his successor at the Berlin Museum, but was himself a doctoral student of P. W. Terentyev in Leningrad (now St. Petersburg)! These few errors do not by any means lessen the great value of this important overview of academic genealogies.

In conclusion, Volume 2 of Kraig Adler's *Contributions to the History of Herpetology* is a monumental work and a landmark in this special discipline. Nevertheless, despite the admiration for this book and for all the great personalities included in it, the herpetological reader certainly still appreciates belonging to the "Herpetologists of the Present."

e-mail: bkwilliams@mizzou.edu

In the preface to *The Ecology and Behavior of Amphibians*, Kentwood Wells muses that the book has resembled at times during its approximate 25-year development "one of those never-ending scholarly endeavors...[like] writing the definitive multivolume biography of Herman Melville." In fact, the book does resemble Melville's famous white cetacean in size, with a final page count of 1148. Despite the rather intimidating size of the book, however, the text is enjoyable. Wells' scholarly endeavor aims to be a single-volume synthesis of major themes in amphibian ecology and behavior and, given the ambitious nature of the task, he is remarkably successful.

The book is organized into 16 chapters, grouped roughly by topic. In each, Wells does a skillful job of discussing volumes of literature with clarity and a strong sense of historical perspective. The book's strength also comes from what Wells chooses *not* to write. Acknowledging that many topics are simply beyond the scope of a single volume, he frequently defers to more specific works. The result is a uncommon balance between depth and breadth of coverage.

For a volume of this scope and size, the book is surprisingly readable. Wells' conversational writing style contributes to this readability, as do the abundant photos, line drawings, and figures. It is rare to see more than four consecutive pages without a visual aid. Full- or half-page photo spreads are distributed throughout the text and, while black-and-white, are generally of high quality. Figures have been reproduced in a consistent format and the book's numerous line drawings (many by Mary Jane Spring) are excellent. Smaller aesthetic details should be appreciated, as well — for example, the matte-finish pages and clear printing. Editorially, the book contains very few typographical errors, which should reduce unwanted distractions from the text for those prone to be grammar and spelling sticklers.

Certainly this book could serve as a reference volume for anyone working on ecological questions involving amphibians. Portions of the book could be used in upper-level undergraduate courses, although its full potential would be better realized in a class of graduate students possessing the background to decipher sections that might prove incomprehensible to many undergraduates (such as the discussion of functional morphology of tadpole feeding). In fact, any graduate student in amphibian biology would do well to spend the first month of his or her graduate career immersed in this book. Students would emerge with a solid foundation in the discipline to which they plan to contribute and a fistful of project ideas, as Wells concludes nearly every chapter with a description of fruitful areas of future research.

In Chapter 1, Wells discusses the evolutionary origins of amphibians and introduces two evolutionary trends in the group — miniaturization and large genome size. Profiles of all recognized families of anurans, urodeles, and caecilians follow. The photos accompanying these descriptions of amphibian diversity also indicate where additional photos of members of each family can be found in the text. Some readers may criticize Wells' decision not to incorporate the taxonomic revisions of Frost et al. (2006), but others will appreciate the continuity of the more traditional nomenclature. The chapter ends — as does each subsequent chapter — with a "Summary and Conclusions" section.

Chapters 2 and 3 discuss two key influences on amphibian ecology and behavior: 1) water relations and 2) temperature relations. As Wells points out with historical quotes, amphibians' close association with moisture and ambient temperatures led some early naturalists to conclude that they were "little more than a peculiar type of fish which is capable of walking on land." In fact, even in *The Biology of the Amphibia* (1931), G. Kingsley Noble remarked that they "remain slaves to their surroundings." As these chapters illustrate, however, amphibians have developed unique ways to capitalize on temporally variable resources despite physiological constraints.

The respiratory and metabolic characteristics of amphibians dramatically reduce their maintenance energy demands, allowing this "defeated group" (as described by yet another early naturalist) to exploit niches unavailable to other vertebrates. These traits have even facilitated the evolution of the world's largest known lungless tetrapod—a typhlonectid caecilian. Chapters 4 and 5 focus on these unique modes of respiration and metabolism, respec-

tively. Wells celebrates the contributions of amphibians, and particularly anurans, to early experimental studies of gas exchange and energetics, although some readers may cringe at descriptions of frogs in vacuum chambers, frogs coated in paint, and frogs buried alive in stone chambers for years. On a less macabre note, the chapter also covers important aspects of amphibian ecophysiology and ecology, such as relationships between oxygen demand and egg size.

Chapter 6 discusses studies of amphibian movement and orientation. The initial section of the chapter focuses on the problems of marking and adequately tracking amphibians, as well as the danger of overestimating home range sizes. And despite an extensive history of work on orientation behavior, Wells is forced to conclude that we do not have an adequate understanding of how amphibians integrate sensory information from various channels to navigate through the landscape. He does, however, summarize movement distances and home ranges reported in the literature for salamanders and terrestrial anurans in several tables, and discusses the relevance of movement behavior for genetic structure and amphibian conservation efforts.

Chapters 7 and 8 cover vocal communication, mating systems, and sexual selection in anurans. Beginning with a description of sound production, Wells moves on to vocal interactions within a chorus and between individual males, as well as female responses to calling behavior. Some sections (e.g., on the processing of acoustic signals) may be compelling reading for a relatively narrow audience, but overall this chapter is a thorough treatment of some of the most intriguing behavioral interactions of anurans. In Chapter 8, Wells refers to his own (1977) review of anuran mating systems and explores three main mating strategies — scramble competition, chorusing and leks, and resource defense. A particularly interesting section of this chapter covers the empirical evidence (or lack thereof) for the ability of females to detect differences in male quality and the likelihood of genetic benefits to offspring as a result of female choice.

Compared to that of anurans, the body of work on urodele and especially caecilian communication and social behavior is modest, although some species have been studied in detail (e.g., *Plethodon cinereus*). Chapter 9 covers a stunning variety of urodele social behaviors and contains some of the book's most impressive line drawings. In addition to describing elaborate courtship displays, pheromone delivery, and territorial aggression, Wells places many of these behaviors in a phylogenetic context. Throughout the book, the importance of phylogenetically controlled studies to support basic biological predictions is a recurrent theme.

Chapter 10 begins with a 17th-century description of amphibian mating, "…with croaking voices the male provoketh the female to carnal copulation," which must be one of the most colorful quotes in the book. In this chapter Wells discusses the natural history of amphibian reproduction, including the segregation of fertilization and oviposition in space and time associated with internal fertilization. He also contributes his own meta-analysis of data on the relationship between egg size, clutch size, and reproductive mode. Based on the results, he argues that the generally reported direct tradeoff between egg size and clutch size in amphibians does not necessarily apply to species within all reproductive modes. Although he points out the limitations of sorting species into these defined reproductive modes, Wells does include descriptions of the 39 modes of Haddad and Prado (2005), grouped by ecological similarity.

Chapter 11 then covers parental care, specifically the evolution of parental care and sex roles and what Wells argues are the different selective pressures giving rise to parental care in anurans versus urodeles. This chapter also contains some of the more extraordinary photos in the book. One of my personal favorites is the series depicting a female African shovel-nosed frog digging out of a subterranean burrow and making her way down to the water, while a cluster of tadpoles clings to her back and the rest follow along behind in a mud channel of her own construction.

The following two chapters focus on the larval stage of amphibian lifecycles, beginning with the ecology and behavior of larvae in Chapter 12. Much of this section is devoted to the ecological morphology of tadpoles, with detailed drawings of lateral views and mouthparts (and several scanning electron micrographs of the latter) illustrating frequent convergent evolution among different anuran families. A discussion of kin recognition and its significance for social behaviors in both anuran and urodele larvae is also included. Chapter 13 then moves into the adaptive significance of complex life cycles and the ecology of amphibian development and metamorphosis. This is a particularly information-rich chapter, dealing with classic models of amphibian metamorphosis as well as paedomorphosis. Through Wells' skills in synthesis, large numbers of relevant papers are condensed into a series of figures and concise descriptions.

Chapter 14 addresses the role that amphibians play as prey for many organisms, as well as the ways predation can influence both individual amphibians and amphibian community structure. Although the descriptions of predators run a bit long, the cleverly named section "Man the Frog Hunter" gives an intriguing history of frog consumption by humans, including an account of 1,000 frogs served at a 16th-century banquet for Elizabeth of Austria. This section mentions the food-related exploitation of *Rana draytonii* and subsequent introduction of *Rana catesbeiana* in the western U.S., but could have also included issues associated with the importation and introduction of *Rana ridibunda* in western Europe.

The influence of predation on amphibian community structure is discussed further in Chapter 15, along with the influences of competition, hydroperiod, and canopy cover. This chapter is an invaluable reference for anyone interested in experimental ecology (as well as a nice primer on work from the labs of Henry Wilbur and Earl Werner). Wells discusses the influence of experimental venue on outcomes of competition experiments and points out that knowledge of terrestrial anuran communities is almost entirely lacking.

One benefit of a lengthy literary gestation period is the ability to incorporate emerging developments. Wells notes at the beginning of Chapter 16 that as evidence accumulated for worldwide amphibian population declines, his original concept of the book's final chapter evolved into a chapter on amphibian conservation. He stresses that basic amphibian biology should be the foundation of any research program on declines. In fact, he builds from this foundation in each of the main sections of the chapter — first discussing amphibian traits that influence vulnerability to environmental perturbations, then exploring causes of declines within a geographic context, and finally asking how ecosystems might

change if there were no amphibians. The concluding section addresses the future of amphibians. Wells' emphasis in this section on the intertwined needs of humans and wildlife in tropical hotspots is refreshing, given that the sociology of conservation could have easily been overlooked in a book of this sort. The chapter ends with a call for hope, outlining specific actions necessary to ensure the continued existence of frogs, salamanders, and caecilians.

In short, *The Ecology and Behavior of Amphibians* makes a weighty contribution to amphibian biology (in more than one sense of the word). Wells has distilled an amazing volume of literature into a single publication. I can recommend this book without reservation to anyone working with, or seriously interested in, the charismatic taxon that Linnaeus once famously dismissed as "loathsome animals."

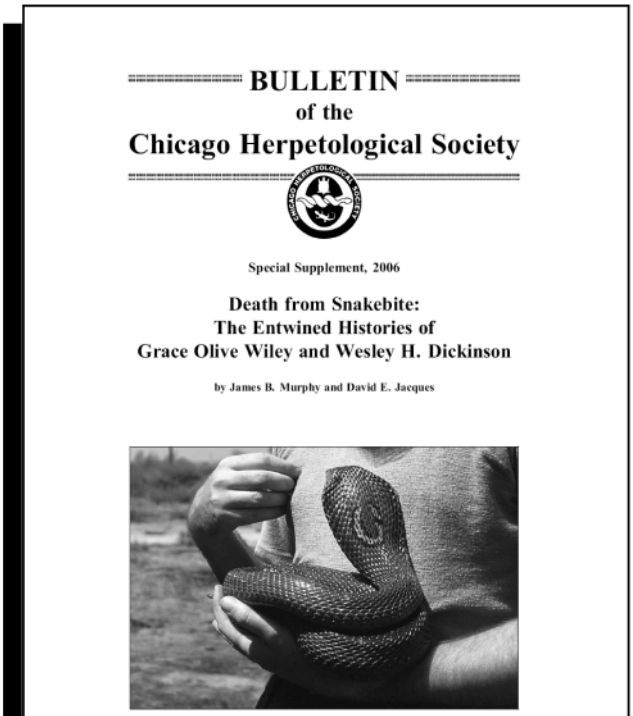
Malformed Frogs

The Collapse of Aquatic Ecosystems



MICHAEL LANNOO

"A comprehensive and up-to-date assessment of the malformed frog phenomenon and its likely causes, as well as its possible relation to environmentally mediated malformations in humans. It immediately ranks as a definitive source for information regarding malformed frogs in the larger context of global amphibian declines."

—James Hanken, Alexander Agassiz Professor of Zoology, Curator in Herpetology, and Director, Museum of Comparative Zoology, Harvard University

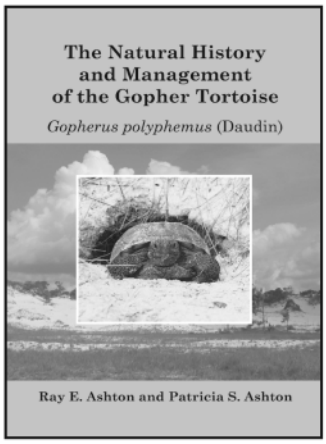
An Updated Guide to Herpetology Terminology



DICTIONARY OF HERPETOLOGY

by Harvey B. Lillywhite

Orig. Ed. 2008 384 pp. Hard Cover ISBN 1-57524-023-8 $112.50

Following the historical precedent of Peters (1964), the new updated *Dictionary of Herpetology* provides a comprehensive, single-volume dictionary, with selected cross-referenced entries to clarify the many technical terms and concepts that pertain to herpetology. The *Dictionary* provides a complete collection of words that are central to understanding the biology of amphibians and reptiles, offering concise and easy-to-use readable definitions in an A-to-Z format that contains 11,358 entries. This reference is essential for students, professionals, breeders, or anyone who is interested in herpetology and its many interdisciplinary connections. The new *Dictionary* emphasizes terminology related to anatomy, physiology, systematics, evolution, and other disciplines, including newly emerged fields that are relevant to the study of amphibians and reptiles.

Science and Conservation of Vernal Pools

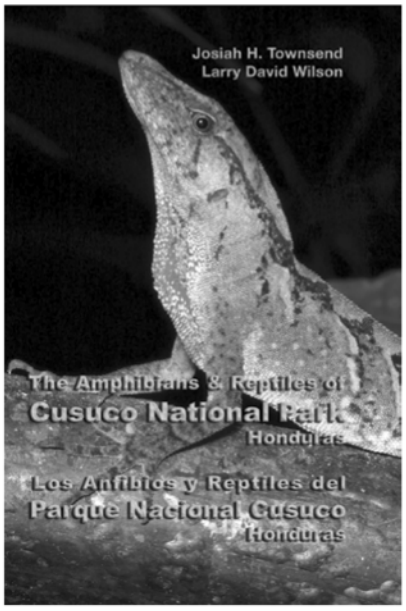
In Northeastern North America

ORDER NOW AND TAKE 20% OFF!

ARAM J. K. CALHOUN • UNIVERSITY OF MAINE, ORONO, USA
PHILLIP G. DEMAYNADIER • MAINE DEPARTMENT OF INLAND FISHERIES AND WILDLIFE, BANGOR, USA

Synthesizing decades of information from a broad array of sources, **SCIENCE AND CONSERVATION OF VERNAL POOLS IN NORTHEASTERN NORTH AMERICA** guides you through the science, issues, and solutions surrounding conservation of vernal pools. Drawing on over twenty years of field and research experience, the editors offer case studies and a thorough review of published and unpublished literature to build a science-based approach for understanding and conserving these unique wetland ecosystems.

FEATURES



- Covers a **diversity of topics**, from the physical to the biological to the political, with a focus on the role of seasonal wetlands as integral components of forested landscapes
- Includes **contributions from wetland scientists, ecologists, zoologists, environmental educators, and policy experts,** providing an interdisciplinary understanding of vernal pool ecosystems
- Concludes each chapter with **conservation recommendations** for application by field biologists,resource consultants, land managers, and educators
- Contains **18 color plates illustrating key vernal pool biota** and principles for their conservation

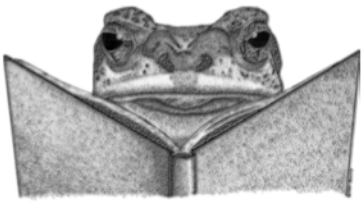
The Amphibians & Reptiles of Cusuco National Park, Honduras

Los Anfibios y Reptiles del Parque Nacional Cusuco, Honduras



Josiah H. Townsend and Larry David Wilson

Cusuco National Park in northeastern Honduras is home to 50 species of amphibians and reptiles, nine of which are endemic to the park. This book, in English and Spanish, is an in-depth guide to the park's herpetofauna.

Specifications: xiv, 322 pages, 6 x 9 inches. Hardcover (ISBN: 978-1-932871-12-8) $44.95 + postage.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution or Natural History notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order form will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor. Regarding missing or damaged issues, please notify *Herpetological Review*, Allen Press, Inc., P.O. Box 1897, Lawrence, KS 66044, USA (tel. 785/843-1234 or e-mail: herps@allenpress.com).

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 840		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2008 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online Allen Press website:

http://timssnet.allenpress.com/ECOMSSAR/timssnet/common/tnt_frontpage.cfm

Future Annual Meetings

2008 — Montreal, Canada, 23–28 July (with ASIH, HL)
2009 — Portland, Oregon, 22–27 July (with ASIH, HL)
2010 — Providence, Rhode Island, 7–12 July (with ASIH, HL)
2011 — Minneapolis, Minnesota, 6–11 July (with ASIH, HL)

About Our Cover: *Zonosaurus maramaintso*

The remarkable herpetofauna of Madagascar remains woefully underexplored. Many species have long been known from single type specimens collected over 100 years ago. However, a resurgence of exploratory interest over the last two decades has yielded new specimens of very poorly known species as well as numerous animals previously undescribed. Among the former is *Zonosaurus boettgeri*, described by Steindachner in 1891 from a single specimen obtained on the island of Nosy Be near the northwestern coast of Madagascar. Field work by Malagasy and American herpetologists beginning in 1993 yielded additional specimens of *Z. boettgeri*, along with new information about its diet and arboreal habits (Raselimanana, Nussbaum, and Raxworthy 2006. Occasional Papers of the Museum of Zoology, University of Michigan, No. 739, 16 pp.). Exploration of the Antsalova region in western Madagascar in late 1996 yielded a single specimen of a new species—*Z. maramaintso*, which seems to be closely related to *Z. boettgeri*. Both species are strongly arboreal canopy specialists, restricted to low elevation primary forests. Likely predators include Serpent Eagles, nocturnal lemurs, and arboreal snakes. Apparently rare—or at least rarely observed—*Z. maramaintso* is known only from an imprecise type locality and warrants conservation attention.

The cover image of *Z. maramaintso* was obtained by **Bill Love** at Olaf Pronk's export compound in Antananarivo. A collector had found the 46 cm long lizard in the Plateau de Bemaraha southwest of the capital, an isolated region of mixed forest and karst limestone ("tsingy") that was virtually unknown herpetologically at the time. Love recorded this image using a Nikon F90X camera with a Nikkor 55mm macro lens, Nikon SB29 ring flash unit, and Fujichrome RVP slide film. Bill is a photographer, writer, lecturer, and ecotour leader through his company Blue Chameleon Ventures (www.BlueChameleon.org). He is perhaps best known for his monthly column in *REPTILES* magazine. Bill resides in rural Lee County, Florida on wild acreage with wife Kathy and their captive colony of corn snakes and other herps.

NEWSNOTES

W. Frank Blair Eminent Naturalist Award

The W. Frank Blair Eminent Naturalist Award recognizes excellence in a lifetime of commitment to outstanding study or conservation of the flora or fauna of the southwestern United States, Mexico, and Central America. For 2007, this award, which is sponsored by the Southwestern Association of Naturalists (SWAN), was given to two herpetologists well known to SSAR members:

PHOTO BY CARL J. FRANKLIN.

PHOTO COURTESY OF KRAIG ADLER

Jonathan A. Campbell (University of Texas at Arlington; above left) and Ernest A. Liner (Houma, Louisiana; above right). The awards were presented at the SWAN annual meeting in Memphis, Tennessee in April 2008. SSAR congratulates Jon and Ernie for this well-deserved recognition.

USGS National Amphibian Atlas

The USGS Patuxent Wildlife Research Center has launched a new website, the National Amphibian Atlas (http://www.pwrc.usgs.gov/naa). This website replaces the former website, ARMI National Atlas for Amphibian Distributions (http://www.pwrc.usgs.gov/armiatlas). The National Amphibian Atlas displays amphibian distribution maps that are a compilation of current and historic records of amphibian occurrences. These maps are based on the original dataset assembled as background for the book edited by Dr. Michael Lannoo, *Amphibian Declines: The Conservation Status of United States Species.* The dataset has been revised to include new information, such as from recent editions of *Herpetological Review* and other sources.

New Features

- Users can select species by common or scientific name
- Maps allow users to zoom in
- Maps display data quality supporting the species occurrence, using 3 color codes to represent museum records, published records, or presumed presence. See website for more information.
- Maps are updated from the former version, which had last been updated in 2004. See Version Information in the Information section for more details.

- Maps will be periodically updated based on data from *Hepetological Review*, Herp Atlases, and other sources.
- Map images can be downloaded for PowerPoint presentations or other uses.

Coming Soon
- Download GIS layers
- View or Download data source information
- Print friendly version of maps

Please help to make better maps
Maps will be periodically updated based on museum and published data, including *Herpetological Review*, Herp Atlas Projects, and other sources. If you have data to contribute, please contact me. All data contributors are credited in the Acknowledgments section on the website.

National Amphibian Atlas website address is: http://www.pwrc.usgs.gov/naa

Contact information:
Linda Weir, USGS Patuxent Wildlife Research Center, 12100 Beech Forest Road, Laurel, Maryland 20708-4038, USA; e-mail: lweir@usgs.gov.

MEETINGS

2008 Gopher Tortoise Council Meeting Announcement and Call for Papers

Please join us for the Annual Meeting of the Gopher Tortoise Council at beautiful Jekyll Island, Georgia, 3–4 October 2008. The meeting will feature a special session on Friday of presentations on Wildlife and Ecosystem Health, with confirmed presentaitons by Elliot Jacobson, Sonya Hernandez Divers, Charles Innis, Steven H. Divers, Terry Norton, John Maerz, Scott Connelly, Nancy Stedman, Lori Wendland, Matt Aresco, Kimberely Andrews, and Greg Lewbart. Saturday the scientific program continues with contributed presentations and posters on any topic relating to the Gopher Tortoise and the Longleaf Pine ecosystem. There will be plenty of time for relaxing and socializing, and enjoying good food and drink at a Low Country Boil Friday night and a Barbecue Saturday night. Also, a tour of the Georgia Sea Turtle Center will be offered Friday evening. For more information and registration information, please visit the Gopher Tortoise Council's website: http://www.gophertortoisecouncil.org/events.php.

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

23–28 July 2008—51st Annual Meeting, Society for the Study of Amphibians and Reptiles; 88th Annual Meeting, American Society of Ichthyologists and Herpetologists; 66th Annual Meeting, The Herpetologists' League. Montreal, Quebec, Canada. Information: http://www.dce.ksu.edu/jointmeeting/

17–20 August 2008—6th World Congress of Herpetology, Manaus, Brazil (meeting jointly with SSAR). Information: http://www.worldcongressofherpetology.org/index.php?section=51

3–4 October 2008—Annual Meeting of the Gopher Tortoise Council, Jekyll Island, Georgia, USA. Refer to meeting announcement above.

24–29 November 2008—VIII Latin-American Congress of Herpetology (VIII Congreso Latinoamericano de Herpetologia), Topes de Collantes, Sancti Spiritus, Cuba. Information: Roberto Alonso Bosch (e-mail: 8voclah@fbio.uh.cu or ralonso@ecologia.cu).

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **Joshua Hale** or **Ben Lowe**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Assessment of Two Antivenoms for Coral Snakes

There are three species of coral snakes within the United States and all are considered extremely lethal. However, as one of them, *Micruroides euryxanthus*, is elusive, only two species, *Micrurus tener tener* and *Micrurus fulvius fulvius*, are considered medically relevant. Medical intervention involves treatment with antivenom, and while no deaths have been reported since antivenom became available, previously 10% of cases proved fatal. The North American Coral Snake Anitvenom (NACSA), produced by the pharmaceutical company Wyeth, was discontinued in 2006, necessitating development of an alternative antivenom. In this study, the authors compared the NACSA with Carolmyn, an antivenom produced by Mexican company Bioclon. The results of a number of trials using laboratory mice demonstrated that *M. f. fulvius* venom was 3.4 times more toxic than *M. t. tener* venom, consistent with past research. Importantly, results indicated that Carolmyn is more effective than NACSA at neutralizing venom from both clinically important coral snake species, with Carolmyn therefore representing a viable replacement for NASCA.

Sánchez, E. E., J. C. Lopez-Johnston, A. Rodriguez-Acosta, and J. C. Pérez. 2008. Neutralization of two North American coral snake venoms with United States and Mexican antivenoms. Toxicon 51:297–303.

Prey-specific Predatory Behavior in a Snake

In predator-prey relationships, selection is generally much stronger on the prey, which may lose its life, than on the predator, which is only risking a meal. However, this situation is different when the prey is toxic. The Floodplain Death Adder, *Acanthophis praelongus*, from Northern Australia, feeds primarily on frogs. Of these frogs, some are non-toxic, like *Litoria nasuta*, others secrete sticky mucous, like *Limnodynastes convexiusculus*, and one species, *Litoria dahlia*, is highly toxic. Observation trials revealed that adders consume these prey items in different and specific ways. While non-toxic prey were consumed immediately, other taxa were envenomated, released, and consumed at a later time. As the toxins and glue-like mucous degrade within about 20 minutes, adders circumvent prey defenses by delaying consumption. The authors suggest that this highly specific predatory behavior is a consequence of the selective asymmetry operating on the predator and prey.

PHILLIPS, B., AND R. SHINE. 2007. When dinner is dangerous: toxic frogs elicit species-specific responses from a generalist predator. The American Naturalist 170:936–942.

Traffic Noise Masks Frog Calls

As reproduction in anurans is highly dependent on auditory communication, they are particularly vulnerable to anthropogenic noise which may interfere with calling behavior. Road traffic is a common source of anthropogenic noise. In this study, the authors tested the impact of traffic noise on acoustic signaling in the Grey Treefrog, *Hyla chrysoscelis*, in Minnesota. Females in amplexus were collected in the field and transported to the laboratory where they underwent a number of phonotaxis trials. Females were presented with recorded calls at one of nine signal levels (37–85 dB at 6 dB increments), without background noise, with a simulated chorus, or with recorded traffic noise. In trials where the signal was masked by traffic noise or the simulated chorus, females took longer to respond (by moving toward the signal source), and only responded to relatively loud signals. Although anthropogenic noise may significantly interfere with acoustic signaling in anurans, the authors suggest that more study is required to understand how plastic behavioral or physiological responses may potentially overcome this interference.

BEE, M. A., AND E. M. SWANSON. 2007. Auditory masking of anuran advertisement calls by road traffic noise. Animal Behaviour 74:1765–1776.

Survey of Chytrid Fungus in Hong Kong

Chytridiomycosis has been implicated in the decline and extinction of a number of amphibian species globally. *Batrachochytrium dendrobatidis*, the pathogen that causes Chytridiomycosis, is present in wild populations on every continent except Asia. However, little research has been completed in this region. For this study, the authors conducted a large scale survey for *B. dendrobatidis* in Hong Kong, the first systematic survey of this type undertaken in Asia. Four species of native amphibians, considered at high risk of infection, were examined, with none of the 274 individuals testing positive to *B. dendrobatidis* infection. A large number of amphibians are imported into Hong Kong each year as part of the pet and food trade representing a possible means of pathogen transmission. Despite this, the authors did not detect *B. dendrobatidis* on any of the 137 imported amphibians sampled. The authors concluded that, until it is confirmed that *B. dendrobatidis* is present in Hong Kong, management effort should be targeted at preventing it from entering the country and spreading into wild populations.

ROWLEY, J. J. L., S. K. F. CHAN, W. S. TANG, R. SPEARE, L. F. SKERRATT, R. A. ALFORD, K. S. CHEUNG, C. Y. HO, AND R. CAMPBELL. 2007. Survey for the amphibian chytrid *Batrachochytrium dendrobatidis* in Hong Kong in native amphibians and the international amphibian trade. Diseases of Aquatic Organisms 78:87–95.

Convergence on Ultrasonic Communication in Southeast Asian Frogs

Odorrana tormota (previously *Amolops tormotus*), is the first non-mammalian vertebrate demonstrated to communicate with ultrasound. It is also one of two anuran species that possess tympanic membranes embedded in the skull, similar to mammals. Like *O. tormota*, the other anuran with sunken tympana, *Huia cavitympanum*, is both a southeast Asian member of the family Ranidae, and calls near rushing streams. However, they are not related at the generic level, and their distributions do not overlap. In this study, the authors investigated calls of *H. cavitympanum*, to determine if this species also communicates using ultrasound. Analysis of recordings of spontaneous male calls indicated that this species produces a number of high frequency calls, some of which are entirely ultrasonic. Along with the Blue-throated Hummingbird, *H. cavitympanum* is the only other non-mammalian vertebrate to produce purely ultrasonic vocalizations. The authors suggest that the convergence of call characteristics between *O. tormota* and *H. cavitympanum* may be a response to their calling environment, which is dominated by low frequency ambient stream noise. The authors also suggest that ultrasonic vocalization may confer an energetic advantage.

ARCH, V. S., T. U. GRAFE, AND P. M. NARINS. 2008. Ultrasonic signaling by a Bornean frog. Biology Letters 4:19–22.

Correspondence to: Peter M. Narins, Department of Ecology and Evolutionary Biology and Department of Physiological Science, University of California, Los Angeles, 621 Charles E. Young Drive S., Los Angeles, California 90095, USA; e-mail: pnarins@ucla.edu.

Species, Rather Than Body Size, Determines Social Dominance in Lizards

Large body size often confers a significant advantage in both intra- and interspecific resource competition, generally indicating superior fighting ability or strength. This has proven problematic to confirm experimentally, because if the dominant taxon consists solely of individuals larger than the subordinate taxon, then separating the influence of species from the influence of size becomes difficult. In this study, the authors separated the influence of species identity and body size in interspecific interactions by conducting laboratory shelter-choice trials using five sympatric montane skink species from southeastern Australia**:** *Egernia cunninghami, Egernia saxatilis, Egernia whitii, Eulamprus heatwolei,* and *Eulamprus tympanum*. Combinations of juveniles and adults from a number of the species were forced to compete for a desirable resource (in this case a 'hot' shelter maintained at 36.5°C, in contrast to a 'cold' shelter at 21°C). Interestingly, juveniles of larger species were as successful as conspecific adults at deterring adults of smaller species, even when much smaller than the adults they displaced. Analysis of bite force confirmed that juveniles posed limited threat to large heterospecifics. The authors conclude that in this system, species identity is more important than body size in determining interspecific dominance.

LANGKILDE, T., AND R. SHINE. 2007. Interspecific conflict in lizards: social dominance depends upon an individual's species not its body size. Austral Ecology 32:869–877.

Correspondence to: Tracy Langkilde, Department of Biology, 208 Mueller Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802, USA; e-mail: t1130@psu.edu.

Identifying Divergent mtDNA Lineages in a Lizard

Molecular research on hybrid zones has primarily focused on mtDNA, which displays substantial variation both between and within species. However, large scale sequencing is both costly and labor-intensive. In this study, the authors developed a quick, cost effective polymerase chain reaction (PCR)-based method to identify divergent lineages within a contact zone in a North American lizard, eliminating the need to sequence large numbers of individuals. Two highly divergent clades of the Side-blotched Lizard, *Uta stansburiana*, form a contact zone on the peninsula of Baja California in northwestern Mexico. The authors used lineage-selective primers generated from sequence data from 15 individuals to amplify a PCR product diagnostic of each of the two mitochondrial lineages. This assay was then applied to an additional 132 specimens from a transect spanning the contact zone to identify mitochondrial lineages. The authors suggest that this cost effective and reliable technique could be used in other species where diagnostic lineage variation occurs.

LINDELL, J., AND R. W. MURPHY. 2008. Simple identification of mitochondrial lineages in contact zones based on lineage-selective primers. Molecular Ecology Resources 8:66–73.

Correspondence to: Johan Lindell, Department of Ecology and Evolutionary Biology, University of Toronto, 25 Willcocks Street, Toronto, Ontario, Canada M5S 3B2; e-mail: johan.lindell@utoronto.ca.

Cost of Phenotypic Plasticity in the Wood Frog

Phenotypic plasticity can allow an organism to respond to temporal changes in its environment; however, plastic responses in one trait can have negative fitness consequences for another. In this study, the authors examined the impact of a plastic trait expressed at the larval stage on post-metamorphic fitness in the Wood Frog, *Rana sylvatica*. This species breeds in temporary ponds, and can accelerate larval development to avoid desiccation, but this has potential impacts on postmetamorphic immune functioning. To examine this, tadpoles housed in the laboratory were exposed to one of four desiccation treatments. Subsequently, individual immune function was assessed by administering a single phytohaemagglutinin (PHA) injection, which causes inflammation around the injection point, with greater inflammation representing a stronger immune response. Leucocyte counts were also conducted to assess immune functioning. Tadpoles exposed to desiccation developed faster than those from control conditions, but had reduced postmetamorphic immune functioning, as determined by both the PHA injection and leucocyte counts. The authors suggest that this reduction in immune functioning may result from a trade-off between rapid development of traits essential for terrestrial life and traits that may not be immediately important. While the duration of immune depression is currently unknown, the authors suggest that even a temporary period may be highly costly to individuals following metamorphosis.

GERVASI, S. G., AND J. FOUFOPOULOS. 2008. Costs of plasticity: responses to desiccation decrease post-metamorphic immune function in a pond-breeding amphibian. Functional Ecology 22:100–108.

Maternal Care in the Dwarf Newt

Most amphibian species do not demonstrate parental care, and there is an extremely high mortality at aquatic larval stages. However, females of the Dwarf Newt, *Triturus pygmaeus*, from the Iberian Peninsula, may indirectly affect embryonic survival by wrapping their eggs in leaves from aquatic plants. In this study, the authors investigated whether wrapping protects the eggs from contamination by ammonium nitrate, a compound commonly found in fertilizer, and water acidification. First, females were collected in the field (N = 54) and exposed in the laboratory to one of three treatments; water containing ammonium nitrate, acid water or a control treatment. Results indicated that low pH altered oviposition behavior, with the percentage of wrapped eggs lower in the

acid water treatment than in the controls. Second, to investigate the impact of egg wrapping on embryonic survival, pre-wrapped eggs were either unwrapped or left wrapped and then exposed to the three water treatments. In the ammonium nitrate treatment, unwrapped eggs suffered higher mortality than wrapped eggs, but there was no difference in the other treatments. The authors suggested that more research is needed to understand the complex interrelatedness between water pollution and egg wrapping behavior in this species.

Costs of Tail Autotomy in the Cape Dwarf Gecko

The survival benefits of tail autotomy to avoid predation are well established; however, the loss of other tail functions may be costly. In this study, the authors compared the locomotor performance of autotomized and intact Cape Dwarf Geckos, *Lygodactylus capensis*, from Pretoria, South Africa. Intact geckos were tested for escape speed and distance, across both horizontal and vertical surfaces. Geckos were subsequently autotomized and retested. Results of repeated measures ANOVA demonstrated that autotomized geckos were slower than intact geckos on the vertical surface, but that there was no difference in performance on the horizontal surface. The authors propose that the observed differences in performance reflect the tail's importance in supporting the body against the vertical surface. The authors also suggested that the tail may not be of great use in horizontal movement, although more research is required. Finally, the authors discuss the impact of autotomization on behavior, suggesting that autotomized geckos may select denser, more horizontal habitats, to maximize escape speed and avoid predation.

ZOO VIEW

"Crocodilians may perhaps live to a great age: probably longer in the sheltered conditions of captivity than when exposed to the active, combatant, competitive career that is theirs in nature."

—Major Stanley Smyth Flower (1925)

Crocodiles may have been the first zoo animals and they remain mysterious, frightening, yet popular with visitors, due to their large size, predatory habits, and occasional attacks upon humans. In my opinion, the most significant zoo program with crocodilians has been the one at the Bronx Zoo/Wildlife Conservation Society. There have been a number of crocodilian papers on a variety of topics, mostly by F. Wayne King, Herndon Dowling, John Behler, Peter Brazaitis, George Amato, and John Thorbjarnarson. One example is the publication by Dowling and Brazaitis (1966), who recorded size and growth of American and Chinese alligators, and Black Caiman, with extensive data on the Nile Crocodile. They provided a table of weight-length measurements for 14 species. In addition to the titles listed in the paper here by Peter Brazaitis and Joe Abene, staff members at the Zoo have published the following studies, focusing in large part on the protection and conservation of these endangered animals.

Crocodilians have been an important element of the reptile collections at the Bronx Zoo since the original plans for the New York Zoological Park and a reptile house were finalized and set into motion on September 27, 1897. However, the history and evolution of crocodilian science at the Bronx Zoo does not stand alone. It is an inseparable part of the discoveries and achievements that were taking place in a wide range of scientific disciplines by new generations of scientists in many places at the same time. Table 1 provides a time line of crocodilian history and reproduction at the Bronx Zoo from 1900 to the present.

Throughout the 1800s, scientific collections of crocodilians, and the scholars who studied and wrote about them, resided largely in museums and universities located in the world's major cities. Collections included fossils, preserved carcasses, skulls, bones, and dried skins, often collected during expeditions to remote regions of the world. Crocodilians had not escaped the scrutiny of the scientific community and there was a wealth of biological information published in scientific journals and books (Brisbin 1986). Yet, what we knew about crocodilians predominantly involved paleontology, taxonomy, anatomy, and osteology. Despite the existence of fewer than two dozen known species, some of which might grow to lengths in excess of 6 m and regularly eat people, crocodilian species identification was based largely on skulls (Boulenger 1889; Mertens 1943; Mook 1921; Wermuth and Mertens 1961,

TABLE 1. Time-line history of crocodilian science at the Bronx Zoo.

Year	Event
1898	Raymond L. Ditmars, Curator (1898–1942)
1898	Bronx Zoo reptile house opens with American Alligators
1933	Hatched American Alligator eggs taken from the wild
1933	Mixed crocodilian collection exhibited (first time)
1944	John Tee-Van, interim Curator (1943–1945)
1945	Brayton Eddy, Curator (1945–1950)
1951	Dr. James A. Oliver, Curator (1951–1958)
1953	Reptile house renovated for the first time
1954	Peter Brazaitis, tenure as Keeper/Superintendent (1954–1988)
1954	Reptile house reopens with adult American Alligators as central exhibit
1957	Mixed collection emerges
1958	Herndon G. Dowling, Curator (1958–1967)
1960	Four large American Alligators leave reptile house
1960	Smooth-fronted Caiman, *Paleosuchus trigonatus*, unanticipated breeding
1962	Reptile house renovated second time
1963	Crocodilian sexing technique developed (Brazaitis 1966)
1964	First museum quality record keeping system (Dowling and Gilboa 1968)
1964	First attempt to breed Chinese Alligators, *Alligator sinensis*
1965	West African Dwarf Crocodile, *Osteolaemus tetraspis.* unanticipated breeding
1966	Endangered Species Act, amended 1969, 1981, 1988
1966	Crocodilian size and growth documented (Dowling and Brazaitis 1966)
1967	Dr. F. Wayne King, Curator (1967–1973)
1970	First crocodilian genetics study (Cohen and Gans 1970)
1971	Species identification of crocodilian hides and products (King and Brazaitis 1971)
1971	IUCN Crocodile Specialist Group founded
1973	Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES)
1973	Comprehensive identification account of living crocodilians (Brazaitis 1973a)
1973	Identity of *Crocodylus siamensis* confirmed (Brazaitis 1973b)
1973	John L. Behler, Curator (1973–2006)
1974	Second floor renovated to include crocodilian rearing facilities
1977	First successful breeding of Chinese Alligator, *Alligator sinensis* (Behler and Brazaitis 1982)
1977	Les Garrick, Crocodilian behavior studies (Garrick and Lang 1977)
1979	Crocodilian diets modified; improved 1981
1979	First Mugger Crocodile, *Crocodylus palustris* reproduction
1980	Yacare Caiman, *Caiman yacare*, bred (Brazaitis 1986)
1980	Captive breeding protocols implemented/breeding calendar
1980	Chinese Alligator SSP/studbook initiated to coordinate breeding efforts
1980	Siamese Crocodiles, *Crocodylus siamensis*, bred (Brazaitis and Watanabe 1983)
1981	West crocodilian pools retrofitted for multi-species breeding
1981	Black light/Vita light protocols initiated (Townsend and Cole 1985)
1983	Ultrasound scanning of *C. siamensis* eggs (Brazaitis and Watanabe 1983)
1983	Cuban Crocodile, *Crocodylus rhombifer*, bred
1985	Malayan False Gharial, *Tomistoma schlegelii*, bred (Brazaitis 1999)
1986	AZA Crocodilian Advisory Group founded
1988	William Holmstrom, Collection Manager (1988–present)
1988	Dwarf Caiman, *Paleosuchus palpebrosus*, bred
1989	Broad-snouted Caiman, *Caiman latirostris*, bred
2006	Dr. Jennifer Pramuk, Curator (2006–present)

1977; Werner 1933). Medem and Marx (1955) provided one of the first keys to the living New World species of crocodilians. Comprehensive papers on the species identification of living crocodilians, directed toward live animals and visible physical morphology, appeared in the 1970s (Brazaitis 1971, 1973a, 1973b).

What appeared to be lacking were behavioral, natural history, and reproductive data. One of the earliest comprehensive reports on observations and natural history of a crocodilian was made by E. A. McIlhenny of Louisiana in his classic work, *The Alligator's Life History*, first published in 1935, and reprinted in 1987. McIlhenny reported shooting and killing one of the largest wild alligators ever recorded, 584 cm in length, on January 2, 1890.

Probably the most knowledgeable group of crocodilian experts of the 1800s and early 1900s was composed of the hide hunters and crocodilian skin dealers who derived their livelihoods and profits from knowing where and when to find crocodiles. They had to know basic crocodilian behavior and habits if they were to avoid being killed or maimed during the course of their dangerous nightly work of hunting crocodiles. Some crocodile entrepreneurs put their knowledge to use to short-circuit the problem of having to spend numerous uncomfortable nights in mosquito-infested swamps to capture only a handful of crocodiles, or none, by starting crocodile farms in the hope of breeding the animals and increasing manyfold the number of skins they could have available to sell. Rather than sharing their knowledge, much of what they knew about crocodilian reproduction and behavior was kept secret, lest a competitor out-produce them.

Collections of living crocodilians were generally confined to considerably less than natural circumstances of captivity in private roadside attractions, circuses, and zoos, and they were managed by entertainment entrepreneurs. The Saint Augustine Alligator Farm, St. Augustine, Florida, opened to the public in May, 1893, is the oldest major exhibitor of crocodilians in the United States. The name is a misnomer as it was never a "farm" for breeding and producing alligators. The Alligator Farm, as it is still locally referred to, is now a registered national historical site and exhibits all of the 23 generally accepted species of crocodilians under natural conditions. The Alligator Farm is considered a world center for crocodilian study, reproductive biology, and conservation, and serves as an important repository and bank for crocodilians that are potentially part of captive endangered species breeding programs.

Zoos probably contributed least to the then-known lexicon of crocodilian knowledge. Space was limited and better devoted to large mammals and colorful birds that were more in the public or zoo director's interest. In the 1800s, exotic birds already enjoyed a great scientific following, augmented by a global cadre of serious collectors and breeders of live birds, who produced a wealth of scientific and popular writings. We knew a lot about birds and mammals, including that crocodiles were prone to eat some of our favorite species. Reptiles, including crocodilians, were usually reviled by the average zoo visitor, who wished only to see them

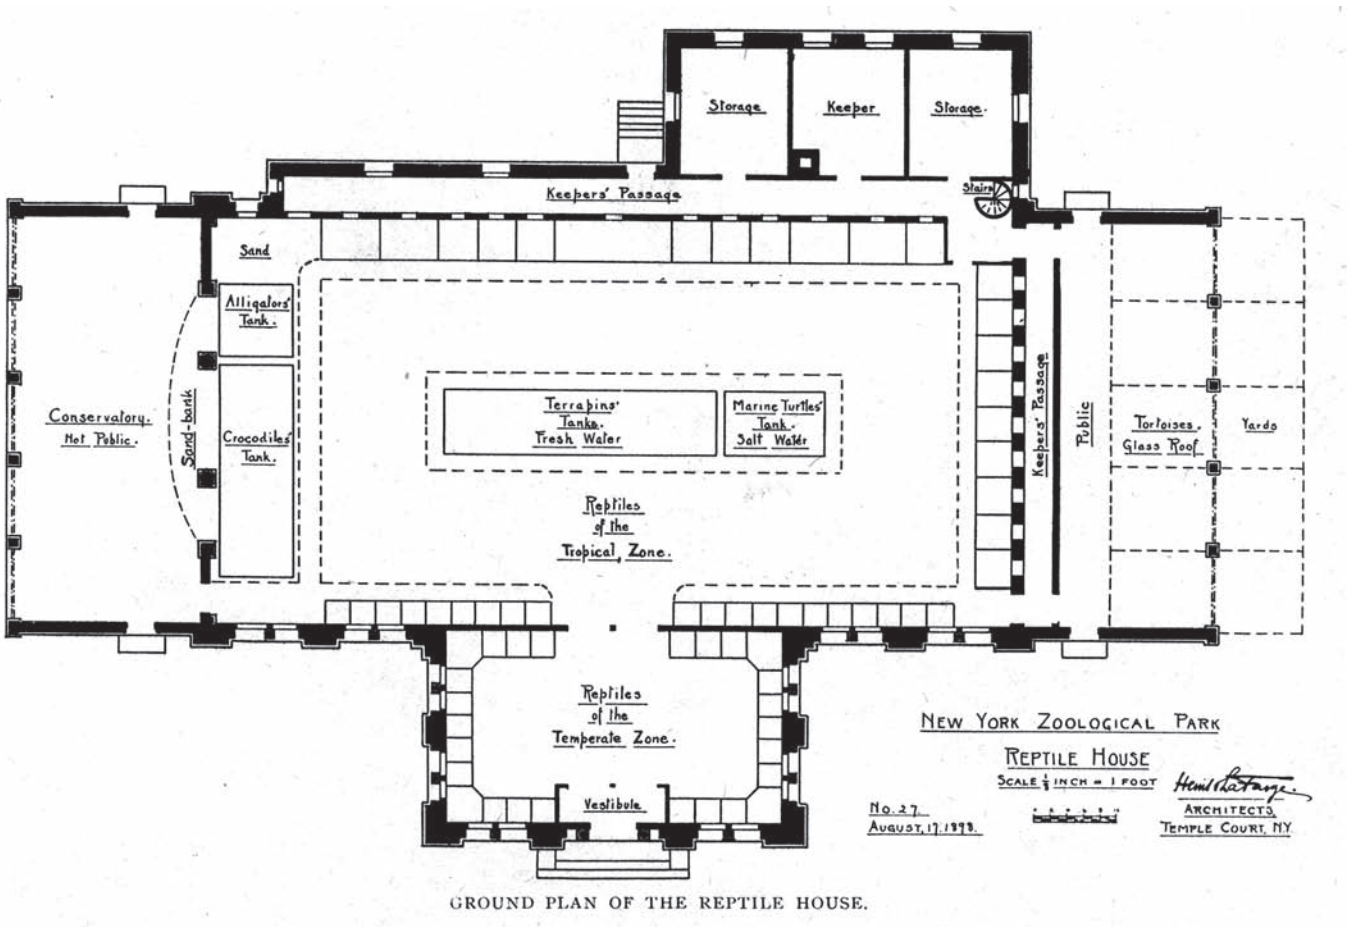

FIG. 1. Original floor plan of the reptile house. The alligator pools are major exhibits at the left, at the west end of the building. They are referred to as "The West Pools."

FIG. 2. The Reptile House at the Bronx Zoo as it appeared in 1898. West pools conservatory is to the left.

out of curiosity as ferocious potential man-eaters. It was generally held, even by the curatorial staff, that as crocodilians inhabited the warm tropical and sub-tropical wetlands of the world, they could be exhibited only at considerable cost in space and utilities if they were to be kept alive at all, especially in northern climates. Certainly, they would not reproduce.

A House for Reptiles in New York City

The Reptile House at the Bronx Zoo was one of the first buildings to be constructed in the newly chartered New York Zoological Park. Opened to the public in 1898, the Reptile House was immediately of immense popularity with the general public. Curator Raymond L. Ditmars (1899–1942) wrote in the zoological society's fifth annual report for 1900: "The Reptile House is permanently fixed in the minds of visitors as a center of attraction," and "All things considered, the alligator pool is perhaps the satisfactory single feature in the Reptile House" (anon., 1898, 1900). Fig. 1. shows the original floorplan of the Reptile House as it was constructed in 1898, in a spacious, state-of-the-art, modern building of the times (Fig. 2). To this day, the exterior of the reptile house remains much as it was originally constructed, a sturdy structure of steel and dense, fire-kilned brick. Its roofline and cornices are festooned with the sculptured cement heads of reptiles and amphibians to mark the presence of its scaly inhabitants. These were especially created by the well known animal sculptor of the time, Mr. A. P. Proctor. The alligator pools at the west end of the building were designed to be main attractions and meant to house only American Alligators (Fig. 3).

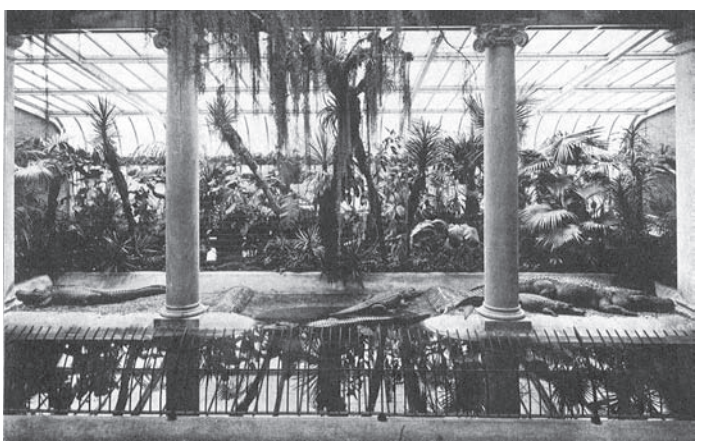

FIG. 3. Alligator pools in the conservatory at the west end of the reptile house in 1900.

Ditmars was well aware that a constant warm environment was essential to the health of crocodilians. He had insisted that heating pipes carrying warm water, immersed along the perimeter of the alligator pools to maintain pool water temperatures in the range of 27–30°C, be included in the construction of the 1898 building.

The Most Beautiful Reptile House in the World

The Reptile House remained largely unaltered until 1954, when, under the curatorship of Dr. James A. Oliver (1951–1958), it underwent its first renovation and modernization. Oliver's article in *Animal Kingdom* was aptly titled, "The most beautiful reptile house in the world" (Oliver 1954). The curved glass-walled conservatory can still be seen, designed to allow the overhead sunlight to brighten the alligator pools and their luxuriant plantings at the west end of the Reptile House (Fig. 4). Oliver's designs for the renovated reptile house advanced the heated pool concept and included a state-of-the art heating system for all of the reptile exhibits, with heated concrete slabs for basking crocodilians. An open nursery with an unobstructed view of juvenile crocodilians was added to the major exhibits, to exhibit the many public donations of alligators. Visitors were treated to a frenzy of crocodilian activity as the keeper staff provided regular feeding demonstrations several times a week (Fig. 5). True to the original concept, the renovated Reptile House exhibited only adult American Alligators, *Alligator mississippiensis*, in the center main pool. However, the east end of the Reptile House now included a spacious crocodile exhibit, patterned after an Egyptian tomb, and a doorway painted with pictograms taken from the *Book of the Dead*, attributed to Sobk, the Egyptian crocodile god, son of Neith (Faulkner 1985). The exhibit housed a single 3.7 m long Nile Crocodile, *Crocodylus niloticus*, named "Joe." The public would be greeted by a bevy of large alligators in a tropical setting as they entered the reptile house and leave with the image of a fearsome maneating crocodile. While the 1954 Reptile House included a nursery for rearing baby crocodilians, a main pool designed to exhibit a few spectacular animals, and two smaller flanking pools for exhibiting special species of interest, there was still no provision for breeding crocodilians, incubating a potentially large number of eggs, or housing a multi-species collection of crocodilians of various sizes and life stages.

The Early Bronx Zoo Collection

The 1900 annual report lists two species of crocodilians in the reptile collection. In September, 1899, Ditmars specifically called attention to the rapid growth of a 395 cm long alligator (Ditmars 1900) (Fig. 6). However, it is unclear how extensive a plan there was for increasing the diversity of crocodilian species in the Bronx Zoo collections between 1898 and the first major renovation in 1954. In the original zoo plan, there was some limited space for

small crocodilians but only two primary exhibit pools and no holding enclosures for larger animals. The exhibition of American Alligators in the main pool was an absolute given, while the acquisition of crocodilians of other species was most often one of chance rather than of design. Crocodilians, like all reptiles, were freely available in the exotic pet trade to anyone who might wish such a pet. Inevitably, if the pet survived poor care, it might be brought to the Reptile House as a donation. Such donations were commonplace, were routinely accepted, and were added to the collection without medical quarantine or concern for possible infectious diseases.

Ditmars proudly wrote in 1913 that the crocodile nursery displayed a mound of baby American Alligators, brought to the zoo by tourists who had vacationed in Florida, and a few crocodiles. By then, he reported that the collection included a number of rare species that included the Indian Gharial, *Gavialis gangeticus*; Senegal Crocodile (West African Slender-snouted Crocodile), *Crocodylus cataphractus*; Salt Marsh Crocodile (Saltwater Crocodile), *Crocodylus porosus*; Orinoco Crocodile, *Crocodylus intermedius*; American Crocodile, *Crocodylus acutus*; West African Broad-nosed Crocodile, *Osteolaemus tetraspis*; and Rough-eyed Caiman (spectacled caiman), *Caiman crocodilus*, as well as American Alligators (Ditmars 1913). Ditmars eloquently wrote of his visit to a ship, "a big freighter from the east," in New York harbor, whose holds were crammed with cages and boxes of large cats, hoofed stock, giant snakes, and crocodiles in long boxes, of which he purchased three. Ditmars did not have easy access to the scholarly literature, and had to depend on the dealers' anecdotal information for origin and species when he purchased animals for the zoo collections. We know that C. Ralph DeSola (1933) published a comprehensive article on crocodilians in the *Zoological Society Bulletin*, with a foreword by Ditmars, that suggested that a number of crocodilian species were on hand, and that the general philosophy among zoological institutions of the period was to outcompete each other by virtue of the number and rarity of species they exhibited. An outdoor pool located immediately to the east of the Reptile House, useable for crocodilians only during warm summer months, is shown to contain a number of basking animals, including several alligators and a crocodile (Fig. 7).

FIG. 4. The west alligator pools as they appeared in 1954, after the first reptile house renovation since 1898. The modernized configuration and supporting columns remain true to the original 1898 floor plan. The center pool houses four large alligators. Two smaller pools, designed to hold smaller crocodilians, lie just out of sight to the left and right. The large alligators were replaced with a multi-species group in the early 1960s.

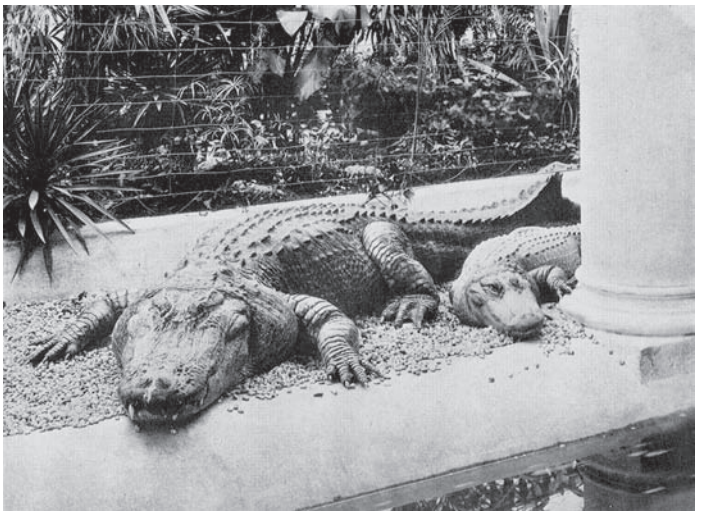
Lack of Technology

No good record-keeping system for the reptile collection existed until 1964. Records included a small box of index cards on the head keeper's desk, with a card for each animal marked #1, 2, 3, etc. within each species. Should #2 die, the next animal of that species to arrive would assume the position of #2. Thus, it is retroactively impossible to track longevity of any individual animal within the collection other than, perhaps, an animal that might have some special notoriety attached to it. Herndon G. Dowling assumed the department curatorship in 1958 (1958–1966) and soon initiated a museum-based system of records keeping that included the permanent marking of individual animals for identification and a system of cataloging the collections (Dowling and Gilboa 1968). One of us (Brazaitis) had been unofficially recording crocodilian size data for many years, and the publication of these data gave the crocodilian collection new value, as a wide range of captive crocodilian growth data would be critical for planning future programs (Dowling and Brazaitis 1966). Dowling brought with him a new direction that positioned the collection and staff for a leap forward in science and the new era of conservation that was at hand.

A number of basic technological issues needed to be resolved before crocodilian collections could gain the scientific importance that avian collections had achieved after many bird species had been decimated by the milliners demand for fashionable feathers and commercial hunters had obliterated passenger pigeon populations. Globally, crocodilians had suffered a similar fate. The wild populations for most species were abusively over-utilized for the skin and pet trades, species were disappearing from many wild places, and even populations of common species were plummeting. The state of the art at the Bronx Zoo mirrored the state of the art throughout the zoological community: collection management and conservation were not yet in sight.

The sex of animals in the crocodilian collection generally re-

FIG. 5. A crocodilian nursery and public feeding enhanced the visitor experience in the modernized reptile house in 1954.



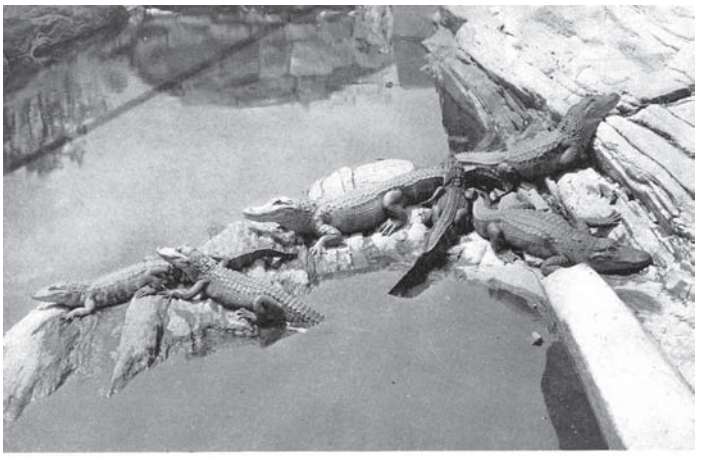


FIG. 6. A 3.9 m (12' 11$^1/_2$") American Alligator was a center of attraction in the 1898 reptile house.

mained unknown until they grew to adult sizes and displayed what might be construed as male behavior. Mature males might be identified, but the identification of females often remained dubious. Animals that might have been maintained for years in the hope of future reproduction might ultimately be found to be of the same sex. When Brazaitis arrived as a keeper in the reptile house (1954), the main west pools housed four large alligators, acquired in the hope that they constituted two breeding pairs. As they grew in size, their incessant combats led to their medication with hormones in an effort to reduce their belligerence. The animals were eventually disposed of to an animal dealer and the main pools were then dedicated to holding the array of crocodilian species that were accumulating.

Fig. 8 shows the northeast pool and two Indian Gharial, *Gavialis gangeticus*. The animal in the foreground lacks a lower jaw and was the oldest crocodilian in the collection, having been purchased for $100 from an animal dealer in 1946. Its importance as a rare species was immediately recognized. Measuring 116 cm on arrival, the animal was presumed to be a female. In 1954, at about 178 cm in length, the animal damaged its lower jaw in a gate accident and the lower jaw was amputated immediately anterior to the mandibular symphysis, at about the 20th mandibular tooth. Thereafter, all feeding had to be accomplished by a keeper using a long forceps, holding food in the animal's mouth until it could be swallowed. The animal thoroughly learned the technique and trained many new keepers, including Brazaitis, in its use. It died of unknown causes in 1974 at a length of 295 cm, having been in the collection for about 28 years. The second animal in Fig. 8 is one of four animals acquired around 1952, for the future opening of the newly renovated Reptile House. The sex of these animals was unknown, and all eventually perished from causes of undetermined etiology. Not until 1985, with the opening of Jungle World in the Wild Asia exhibit at the Bronx Zoo was the species exhibited again. five sub-adult gharial from Orissa, India, were added to the collection, to become the nucleus of a future captive breeding program for this critically endangered species.

Still, by 1954, there was no plan for breeding crocodilians**.** It was not until 1963 that a reliable method of sexing crocodilians was discovered at the Reptile House (Brazaitis 1969), when five American Alligators were placed on their backs and compared for any sexual dimorphism. The management of crocodilian collections, planned reproduction, and the interpretation of behaviors was now possible.

However, breeding potential was still haphazard. Most crocodilians died well before maturity due to dietary deficiencies or conflicts with larger animals as they approached adulthood. Rapidly growing juvenile crocodilians often suffered developmental anomalies. For food, zoos generally provided only those species of fish that were commercially available in human food markets, and it was yet unknown that certain fatty saltwater species, particularly after being frozen and thawed, were detrimental to crocodilians, prohibiting the absorption of critically needed vitamins and minerals, and adversely affecting fertility. Frozen saltwater fish, horsemeat, liver and heart meats, as well as all vitamin supplements, were removed from all crocodilian diets beginning in September 1979 and replaced with fresh-killed whole rodents, poultry, and live freshwater fish. In addition, color-corrected and ultraviolet lighting regimens, developed by Townsend and Cole (1985) at the American Museum of Natural History for enhancing reproduction of parthenogenic lizards, were applied to hatchling and rapidly growing crocodilians and proved equally successful. The management changes precipitated an unparalleled era of reproductive success.

Golden Age of Discovery in Crocodilian Science

Our ignorance of crocodilian behavior and reproductive biology was quickly being dissipated by a cadre of new scientists, inspired by awareness of the plight of threatened and critically endangered species. We had been working in the "dark ages" by the "seat of our pants," and there seemed to be no time left as species populations were designated by the international community as either threatened or endangered.

Ted Joanen, of the Louisiana Department of Fur, Fish and Game, was perhaps one of the most forward and practical thinkers of the times in conservation biology. Joanen understood the need for endangered species to have value if they were to be preserved for future generations, and he also set about developing management

FIG. 8. Indian Gharial, about 1957. The animal on the left has lower jaw amputated as a result of an earlier injury. It survived for more than 26 years by hand feeding. Photo by Peter Brazaitis.

protocols for captive breeding and husbandry that still stand as a model. Tracts of various types of alligator habitats were identified in Louisiana, along with their endemic alligator populations and ecology, to monitor the effects of human and natural predation, weather, and environmental changes on population dynamics, nesting, and reproductive success. Most important, a population of captive alligators was established under intensive control and study to compare the success of captive management techniques with the reproductive success of wild populations. His was the only study of its kind for any species anywhere in the world, where a known population of individually identified crocodilians was continuously monitored and documented through successive generations.

The facilities of the Rockefeller Refuge in Grand Chenier, Louisiana, which Joanen headed, and its invaluable wild and domestic alligator populations provided unparalleled opportunities that were utilized by scientists and students for many years. Data provided comparative standards for the management of wild populations and for developing the husbandry for any species of crocodilians in captivity. Much of what we know of crocodilian reproductive biology and behavior was generated from Joanen, his staff, and their work at Rockefeller Refuge (Joanen 1969; Joanen and McNease 1971, 1975, 1980). Much of this knowledge allowed the State of Louisiana to determine its alligator population and ways to manage it through controlled harvesting. Alligator populations and their habitats became a renewable, desirable, and highly profitable natural resource by allowing for sale of harvested animal hides and meat.

Unfortunately, upon his retirement around 2003, Joanen's domestic captive alligator research population was destroyed for lack of support funding and interest (Joanen, pers. comm.).

While Joanen provided ongoing data on reproduction and captive population management, a new field of animal behavior emerged. Myrna Watanabe, a graduate student from New York University, noted that little was known of maternal behavior in alligators or other crocodilians, and set about to observe alligators attending their nests and throughout the parenting process. In 1976, Watanabe was the first to record the litany of vocalizations and behaviors between mother alligators and their hatching young. Her reports of nest excavation by female alligators to liberate hatching young, of carrying hatchlings to the water in her jaws, and of providing ongoing protection and maternal care documented that true to their evolutionary ancestry, alligators continue to practice behaviors generally attributed to birds (Watanabe 1977, 1979, 1980, 1981, 1982a, 1982b, 1986a). Such observations were transmitted to Bronx zoo staff on a daily basis, as Bronx zoo crocodilians nested and produced offspring.

After first completing American Alligator studies at Rockefeller Wildlife Refuge, Watanabe, fluent in Chinese, continued her research in China, joining with Chinese scientists (Watanabe 1983, 1986a,b) to document the secretive behavior and biology of the Chinese Alligator, *Alligator sinensis*, the only relative of the American Alligator. They provided field data that promoted an understanding of the breeding behaviors of Chinese Alligators in captivity. By then, she estimated that the species had been reduced in the wild to fewer than 500 individuals, and it was designated the most endangered species of crocodilian. Her early reports indicated that nearly all wild individuals and their habitats were close to extinction, and the remaining wild population had been relegated to tree farms and cultivated areas, where they continued to be decimated. The first government-sponsored Chinese Alligator farm was established in 1981. Her collaborations with the Wildlife Conservation Society and National Geographic contributed greatly to the success of the Bronx Zoo's Chinese Alligator propagation program.

In St. Lucia, Natal, South Africa, Anthony (Tony) Pooley was also documenting Nile Crocodile nesting and maternal care behaviors and demonstrated that female crocodiles were so in-tune to the maternal care of their young that he recorded a 4-m-long female Nile Crocodile gently take her hatchling directly from Tony's hand (Pooley 1982; pers. comm.). Other researchers were working to understand crocodilian behaviors as well. Leslie D. Garrick, a crocodilian research intern at the Bronx Zoo, and Jeffrey Lang, then of the University of Minnesota, collaborated at the Zoo to document the social signals of crocodilians (Garrick 1974, 1975; Garrick and Lang 1977); and Kent Vliet, University of Florida, documented alligator social behavior (Vliet 2001) by observing their activities from the alligator's perspective: in the water at alligator eye level. His work continues today to enhance crocodilian reproduction programs at the St. Augustine Alligator Farm and provide guidance for crocodilian captive management programs throughout North America.

Mark W. J. Ferguson (1981), then a professor of anatomy at The Queen's University of Belfast, documented the embryonic development, egg degradation, and embryology of American Alligators, and astonished scientists by reporting that the sex of crocodilians was not determined by chromosomes, but by the temperature that the crocodilian's eggs were subject to during incubation (Ferguson and Joanen 1982). Also, Ferguson used the palatal development of American Alligator embryos to better understand the problem of cleft palate in humans (Ferguson et al. 1983). From these studies, we now know why crocodilian embryos perished so easily during some stages of development and not during others. Rotating crocodilian eggs during critical developmental periods during incubation may cause the embryo to break loose from its egg membranes and die. The incubating egg must also enjoy a fine balance of moisture and gas exchange if the eggshell is to degrade sufficiently during incubation to allow the fully developed embryo to break out of its shell and hatch.

One of the earliest studies of crocodilian genetics was conducted at the Bronx Zoo by human geneticist Maimon Cohen, director of the Cytogenetics Laboratory of the Greater Baltimore Medical Center, and herpetologist Carl Gans (Cohen and Gans 1970). With the advent of molecular genetics technology, a new generation of scientists emerged to give us a fresh look at the relationships among crocodilian species: George Amato, first at the Zoo and now at the American Museum of Natural History (Amato 1991, 1994; Amato et al. 1998); paleontologist Chris Brochu of the University of Iowa (Brochu 2001; Brochu and Densmore 2001), and Lew Densmore of Texas Tech University (Densmore 1983; Densmore and Dessauer 1984; Densmore and Owen 1989; Densmore and White 1991).

Roland A. Coulson and Thomas Hernandez (Coulson and Hernandez 1964, 1983), of Louisiana State University, pioneered work on crocodilian metabolism working with Ted Joanen and his colleagues at Rockefeller Refuge.

The Right Time and the Right Place for Crocodilians

The United Nations Convention on International Trade in Endangered Species of Wild Fauna Flora (CITES) came into being in 1973 and called attention to the alarming depletion of crocodilians worldwide. The Lacey Act of 1900 was broadened and the Black Bass Act of 1926 and the Endangered Species Act (ESA) (1966) were combined and amended, which gave sweeping protections to crocodilian species throughout the world. The exotic reptile leather trade was itself facing extinction as wild populations plummeted and anticipated profits evaporated, because the demands on the resource outstripped the legal and illegal supply of raw skins. In the United States, the American Alligator, the symbol of America's southland, was endangered. The Wildlife Conservation Society (then the New York Zoological Society) and the reptile department were at the heart of the crocodilian conservation movement. F. Wayne King (1967–1973) had succeeded Dowling as Curator of Reptiles and he soon developed a consuming interest in crocodilian conservation, expanding on the crocodilian work begun by Dowling and Brazaitis (1966). King organized a meeting in 1971 between law enforcement agencies, Louisiana and Florida wildlife authorities concerned with the plight of American alligators, and representatives of the exotic leather trade. The first comprehensive work on species identification of crocodilian hides and products was introduced to facilitate wildlife law enforcement (King and Brazaitis 1971) followed by the species identification of living crocodilians (Brazaitis 1973a). These factors provided a huge incentive to develop captive breeding programs.

In this new era at the Zoo, we still had no accommodations for breeding crocodilians, no conviction that crocodilians could be successfully bred in artificial pools, and no official plan to initiate a crocodilian breeding program at the Bronx Zoo. Then, one day in March 1964, a maintenance truck parked behind the Reptile House as the workers enjoyed a coffee break. In the back of the truck was a discarded wooden tub that had served for many years as a temporary pool for a Pigmy Hippopotamus in the Elephant House. It measured about 2.5 m in length, 2 m in width, and 70 cm deep at its deepest end. The reptile house keepers commandeered the half-rotted tub, installed it in the conservatory behind the west pools, and immediately populated it with a trio of Chinese Alligators (Figs. 9, 10). The first Bronx Zoo endangered crocodilian species breeding initiative was born (Brazaitis 1968). Something was missing, however, and no breeding occurred.

The west crocodilian pools and the conservatory areas (Fig. 11) were eventually retrofitted in 1981 to include two off-exhibit breeding pools, five nesting areas, and three main exhibit breeding pools. Conspicuous is the exceptionally small size of the complex and its nesting areas, and, in particular, the shallow nature of the pools. The main exhibit breeding pools (1, 2, 3) are less than 65 cm at their deepest point (Table 2).

A number of endangered species in the collection had now reached sexual maturity, and with improved diets and health, began to display reproductive behavior. Because more than one species, following their own intrinsic breeding cycles, would be breeding within a relatively short time period, it was necessary to establish a "breeding calendar," to anticipate having the appropriate accommodations ready at the right time for the right animals. The calendar indicated what species was anticipated to be breeding during what period, and when the females were scheduled to lay eggs. "Musical crocodiles" became the theme, as males and females of one species after another were scheduled in rotation, first to pair and breed in the main or rear breeding pools. Then, females were isolated in secluded rear pools during gestation and later given access to a nesting enclosure to deposit their eggs. Finally, the female crocodile was rotated out to make room for the next gravid female. Eggs would be removed immediately after laying for artificial incubation in the reptile nursery. Hatchlings and growing young, up to a meter in length, were then reared in galvanized cattle troughs on the second floor of the Reptile House, at about 30–35°C, under black light and color-corrected daylight fluorescent lights. In 1983, eggs of three species of crocodilians were under incubation simultaneously.

To date (2008), 10 species of crocodilians have been successfully bred at the Bronx Zoo. Prior to 1980, unanticipated and unrecorded reproduction had taken place with the hatching of single eggs of West African Dwarf Crocodile, *Osteolaemus tetraspis*, and a Smooth-fronted Caiman, *Paleosuchus trigonatus*, found in the pool water. Behler et al. (1987) provided an overview of crocodilian reproduction at the Bronx Zoo.

A Chronology of Crocodilian Reproduction

Initially, the species we bred were the species that were already on hand. As husbandry techniques were refined and new data on the status of wild populations emerged, captive breeding programs focused and gave priority to the most critically endangered species. Programs evolved to include collaborative efforts among consortiums of interested private individuals, zoological institutions, and governments; the Crocodilian Advisory Group of the American Zoo and Aquarium Association, and the IUCN Crocodile Specialist Group. Dedicated space and resources are limited, and priorities changed as some species and wild populations recovered.

Yacare Caiman, *Caiman yacare*

The Yacare Caiman of the grasslands of central South America deserved special interest. Decimated by excessive hide hunting, it

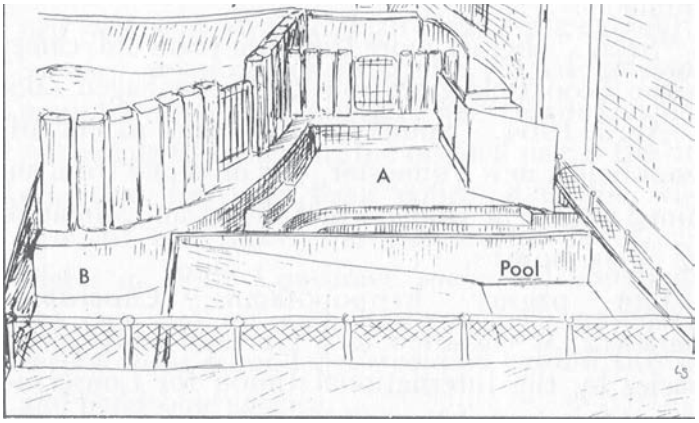

FIG. 9. Chinese Alligator enclosure with old hippo pool, reptile house conservatory, 1964. Illustration by Lloyd Sandford.

was the first crocodilian to be listed as an endangered species under the US ESA on June 2, 1970. Ten hatchling animals, ranging in length from 50–97 cm, were acquired from the U.S. Fish and Wildlife Service in September 1971. An 11-year-old yacare measuring 145 cm in length commenced to lay infertile eggs in 1977 and 1979. Diets prior to 1980 had yet to be improved and consisted largely of frozen saltwater fish and horse and beef meats and Vitamin E supplements. However, with the diet change to fresh-killed small mammals and birds in September 1979, the effect was dramatic. In April 1980, a 137-cm-long female laid four fertile eggs which were successfully incubated and hatched. This was the first of a planned and documented, successful, crocodilian reproduction at the Bronx Zoo (Brazaitis 1986).

Chinese Alligators, *Alligator sinensis*

The odyssey of the Chinese Alligator, a burrowing dwarf species found only in possibly three provinces in southern China (Chen 1990; Huang 1981), beginning with the Bronx Zoo collection, is a global story spanning decades. In 1963, the collection included three Chinese Alligators, which newly developed sexing techniques

FIG. 10. The original pair of Chinese Alligators in the first established breeding pool in 1964. The animal at the rear is the original male estimated to be more than 40 years old at the time. Photo by Peter Brazaitis.

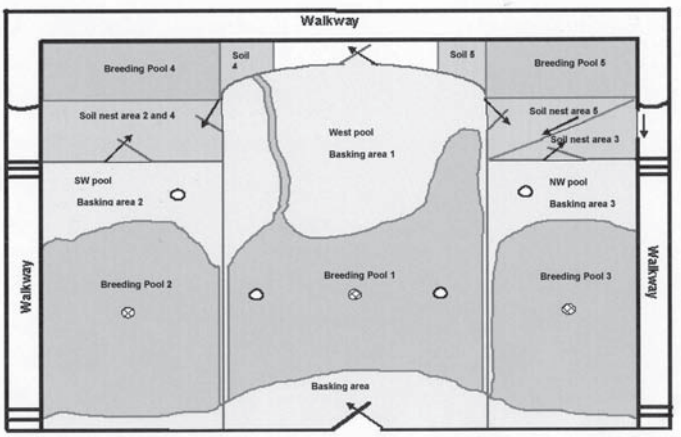

FIG. 11. The west crocodilian pools and the conservatory areas as they were retrofitted to provide a multi-species crocodilian reproduction complex. The complex includes: three primary exhibit and breeding pools (1, 2, 3), exhibit basking areas are bare cement and have imbedded heat coils to enhance basking; two off-exhibit breeding pools (4, 5). See Table 4 for dimensions for breeding pools and nesting areas. Connecting doorways and accesses allow for any crocodilian in any pool to be moved without capture to any pool or nesting area throughout the complex. Keeper staff may view all areas from the elevated walkway around the perimeter of the complex or from the public space. Soils nest areas are filled with a soil/sand/mulch substrate ca. 40–60 cm deep. All nest areas have buried temperature-controlled electric heated pads as attractive nest sites (grids). Nest Box 2 contains less than 30 cm deep substrate and measured ca. 80 × 100 cm in size. Illustration by Peter Brazaitis.

told us were comprised of an adult male and female and a second younger female. It now seemed logical to attempt to breed this small rare species, although the male had been acquired as an adult from Poland in 1956 and was presumed to be at least 40 years old. The trio was established in one of the smaller west pools with a small box of substrate to permit nesting. The older female immediately took over the nest box (Brazaitis 1968). No breeding occurred, although the animals engaged in regular courtship. A second attempt under slightly improved conditions in 1964 also met with failure. The Reptile House effort was abandoned.

In 1975, under the leadership of the late John Behler, who had assumed the curatorship of reptiles in 1973, the program was renewed and expanded to include two animals from the National Zoological Park, in collaboration with the Rockefeller Wildlife Refuge. Two pairs of Chinese Alligators were moved to Rockefeller Refuge in 1976, where a half acre of wetlands and ponds were included in each pair's enclosures. In 1977 the first breeding occurred, resulting in three offspring. The forty-year-old-plus males had sired their first offspring. As in American Alligators, a cold period of hibernation appeared to play a critical role in reproduction. Subsequent breeding occurred in 1978, 1979, and 1980 (Behler and Brazaitis 1982; Brazaitis and Joanen 1984). The program has since produced numerous offspring (Fig. 12), including in a number of satellite zoos, and has evolved into one of the most successful endangered species programs under the Association of Zoos and Aquariums (AZA).

Three Chinese Alligators were sent to China in 2003 to augment the national program to preserve the species. Twelve animals in total, including six males from the Bronx Zoo program

TABLE 2. Dimensions and water depths of the crocodilian breeding complex.

Breeding areas and pools	West pool Area 1	SW pool Area 2	NW pool Area 3	Rear Area 4	Rear Area 5
Pool depth (cm)	49	63.5	43.2	63.5	71.1
Total area (approx m^2)	45	11.8	14.6	8.9	4.9
Pool (approx sq m^2)	18.2	5.7	7.5	5.1	4.9
Basking area (approx sq m^2)	30	5.6	4	na	na

and three females each from St. Augustine and Disney Animal Kingdom, were sent to China in May 2006. The Chinese Alligator breeding centers in China are well funded and emphasize their roles as both tourist attractions and to ensure the survival of the species, at least in captivity (Thorbjarnarson, pers. comm.). Captive individuals now number in the thousands. Field surveys by Watanabe (1982) found, and Thorbjarnarson et al. (2002) confirmed, that the wild population of Chinese Alligators continues to face the prospect of imminent extinction.

Behler officially became the AZA Chinese Alligator studbook keeper in May 1982; this was the first studbook for a reptile breeding program. He was succeeded by Joe Abene, reptile keeper at the Bronx Zoo. The AZA Crocodilian Advisory Group was established in 1986, and the Chinese Alligator program, formally created by Behler in 1980, continues to stand as a model for AZA reptile and amphibian management programs.

Siamese Crocodiles, *Crocodylus siamensis*

Considered virtually extinct in the wild, this species had not been seen in the wild for decades, although older captive animals were the bases of extensive captive breeding for hides and meat in Thailand. The first crocodilians to be seized in 1971 under the new protections (listed as endangered under CITES, 1975; ESA, 1976) were a group of hatchling Siamese Crocodiles without documentation, hidden in an air cargo box at John F. Kennedy International Airport in New York. U.S. Fish and Wildlife Service Special Agents Warren Diffendal and Ed Baker were checking import cargo when they casually tapped on a box labeled machinery and the box began to croak. These 14 youngsters became the first group colony of managed endangered species at the Bronx Zoo, producing offspring almost annually from 1983, at age 12, (Brazaitis and Watanabe 1983) until 1987. They would eventually populate zoos throughout the United States.

Cuban Crocodiles, *Crocodylus rhombifer*

"Fidel" and "Maria" were perhaps two of the most famous crocodilians in US zoos. Fidel (Fig. 16) came to the Bronx Zoo in 1958 from the Tarpon Springs Zoo, Florida, as a juvenile and quickly made his mark by attempting to consume the hand of Brazaitis during a public feeding. The two crocodiles were tightly bonded and remained intolerant of all other crocodiles throughout their lives. Both animals were of immense genetic important to the AZA Cuban Crocodile endangered species propagation program in that they represented pure Cuban Crocodiles from times prior to the commercial hybridization of Cuban and American crocodiles in Cuban crocodile farms. "Fidel" and "Maria" produced numerous offspring: one in 1983, six in 1984, and 21 in 1985.

Indian Mugger Crocodile, *Crocodylus palustris*

Crocodylus palustris was well represented in the collection between 1969 and 1994, with the arrival of a male and a female in 1969. An additional male and two females were acquired from the U.S. Fish and Wildlife Service in 1971. All of the first eggs produced by these animals were infertile and laid in the water, probably as a result of poor diets of saltwater fish during their prereproductive ages, and not having available a nest site with a temperature elevated above the pool water temperature. Typically, pool water temperatures averaged 29°C, while ambient air temperatures might vary from 21 to 26°C during the months from February to April. Prior to the introduction of a heated nesting site in breeding enclosures in 1981, it was not unusual for animals to select for the warmer water as a "nest site" in which to lay their eggs. The pattern of egg production suggests that the reproductive cycle of these animals may well be genetically programmed. In India, *C. palustris* typically lays eggs from February to April in the wild, and averages 28 (10–48 range) eggs per clutch (Lang 1986; Whitaker and Whitaker 1977). Despite having been reared in captivity and subjected to an alien annual photoperiod, lack of natural sunlight, and varying temperatures from the first year throughout maturity, this group of *C. palustris* exhibited a repro-

* Successful breeding with *Crocodylus rhombifer*

ductive cycle that remained typical for the species in its native homeland (Table 3).

Indian Mugger Crocodile, *Crocodylus palustris* × Cuban Crocodile *Crocodylus rhombifer* hybrid.

In 1983, a male *Crocodylus palustris* successfully bred with an approximately 1.5 m long female *Crocodylus rhombifer.* A number of eggs were laid and artificially incubated on 30 April 1983. One egg successfully hatched on 5 July 1983, producing a healthy hybrid crocodile 249 mm in length and weighing 57.2 g. On 13 August 1984, it was transferred to Florida holding facilities. The animal measured 2.5 m in length and weighed 70 kg (Table 3).

Malayan False Gharial, *Tomistoma schlegelli*

Perhaps one of the most exciting breeding successes took place in July, 1985 (Brazaitis 1999) with the hatching of seven animals. The female, 245 cm long at the time of breeding, had been acquired from the San Jose Zoo, California, in 1974 with an injured upper jaw, which was splinted and wired to stabilize the jaw on arrival. The male, acquired in 1974 from an animal dealer, measured 131 cm on arrival, and was ca. 3.6 m long at the time of breeding in 1985. The female built a nest of hay, bark, and sand, in which she buried and guarded 26 eggs. Breeding took place in a pool shared with a third and smaller animal in breeding complex #4 (Fig. 14), in a pool only slightly longer than the larger male's length and half his width, with a water depth of less than 76 cm. However, breeding was never repeated by these young adult animals for unknown reasons. Their offspring have not, as yet, bred. *Tomistoma* in the care of Bruce Shwedick (pers. comm.), in Florida, where his animals are housed under more natural conditions, also have bred only one time to date.

Broad-snouted Caiman, *Caiman latirostris*

Although a lone male was acquired from the U.S. Fish and Wildlife Service in 1971 as an undocumented importation, it was not until October, 1985, that a group of five male and five female, four-year-old animals, ranging in size from 96 to 185 cm, were obtained from the Atagawa Crocodile Farm in Japan. The animals were captive bred and were to become the nucleus of a US captive breeding program. However, the animals appeared somewhat debilitated and undernourished on arrival, and it was not until April 1987 that the first ones began producing fertile eggs. Eighteen eggs hatched in July of 1987; eight in July, 1988; six in July 1990, seven in August 1994, and one each in July,1995 and August 1996. By that time, commercial farming operations were well underway in Argentina. The species was no longer considered endangered and it was downgraded to lower risk by the International Union for the Conservation of Nature and Natural Resources (IUCN).

Dwarf Caiman, *Paleosuchus palpebrosus*

Crocodilian reproduction continues today with the successful breeding of this prolific, secretive, but common northern and central South American species (Medem 1958). A male was collected in Surinam in 1977 and has since bred with two females acquired from the Paramaribo Zoo in Surinam in 1985 (103 cm and 89 cm, respectively). Since then, these animals have produced numerous eggs and hatchlings (Table 4).

Future History

The history of crocodilian breeding and reproduction has gone full circle over the past 107 years, since Ditmars first put a 12 foot long alligator on exhibit in the new Reptile House at the Bronx Zoo, and ecstatically announced the successful hatching of an American Alligator egg the zoo had acquired from a donor. We no longer put animals together whose species identity and sex are uncertain. Molecular science now allows us to selectively pair those individuals that best typify the species' genetic profile and preserve genetic diversity. Our basic concept of what is a species, and which "species" is more closely related to which and what do

we call it, is in flux.

Forty years ago, we learned that, all good intentions aside, the successful breeding of a single female could provide a stock of more animals than all of the facilities provided by most of the United States' zoos combined could maintain. Yet, other than the most critically endangered species, returning some of those animals to the wild to repopulate decimated populations is often neither possible nor practical. Original habitats, because of recent development and human encroachments, may no longer exist in a condition where they can still support crocodilian populations. In some cases, the countries involved may have implemented national breeding and reintroduction programs. The captive propagation of crocodilians has evolved from asking the question, "Can we breed any species at all?" to "What species do we really want to breed, and how often?" In fact, we have opted to not breed most of the 23-odd species of crocodilians because we have come to realize that, collectively, zoos do not have sufficient accommodations or resources to manage long-term captive breeding programs for any but the most critically endangered species, such as the Chinese Alligator and the Philippine Crocodile, *Crocodylus mindorensis*.

TABLE 4. Reproductive success of *Paleosuchus palpebrosus* at the Bronx Zoo.

Female	F Unknown	Hatched	F850075	Hatched	F850076	Hatched
1988	15 eggs	5				
1990			15 eggs	15	13 eggs	12

* Breeding curtailed and egg hatching interrupted. Resumed 2007.

However, the same crocodilian science and technology that allowed the Bronx Zoo to lead the way in captive crocodilian propagation also provided a more lucrative way to save endangered species through commercial propagation. We may yet lose species, not to over-utilization or lack of technology, but to the loss of species identity through the careless breeding of captive animals, disregard for the preservation of the species' genetic integrity, or worse, the large-scale deliberate hybridization of species to produce more prolific crocodilians that are faster growing and have a more valuable skin. The accidental hybridization of *C. palustris* with *C. rhombifer* at the Bronx Zoo in 1983 demonstrates the ease with which crocodilians may interbreed under captive conditions. *C. rhombifer* and American Crocodiles, *C. acutus*, were commercially hybridized for the commercial skin trade in Cuba, and may have compromised the genetic integrity of the Cuban Crocodile. The saltwater Crocodile, *C. porosus*, and the Siamese Crocodile, *C. siamensis*, continue to be hybridized in great numbers for the commercial skin trade in Thailand. In Colombia, commercial caiman skin and meat farms produce millions of skins per year as a product of indiscriminate captive breeding of closely related but distinct *Caiman* species with little regard for population integrity. Non-native crocodilian species continue to be introduced into non-endemic countries to commercially capitalize on a perhaps higher value of skins than those of native species. An example is the commercial introduction of Nile Crocodiles into Brazil for commercial farming. Future zoological historians may yet accuse, and simultaneously congratulate, our generation for developing the skills to produce thousands of individuals of any given species at will in captivity, yet failing to preserve the habitats and wild populations that are our natural wildlife heritage. There may well be tens of thousands of Chinese Alligators in captivity, while the species may yet become extinct in the wild.

Acknowledgments.—This paper is dedicated to the late John Behler, curator of reptiles, The Wildlife Conservation Society. It is not possible to adequately acknowledge the many other scientists and staff whose research made the Bronx Zoo crocodilian programs possible. However, the keeper staff of the reptile department, who daily risked life and limb, without hesitation to capture, move, and work with dangerous crocodilians, simply in the interest of science, deserve special thanks and acknowledgment: Bruce Foster, Kathy Gerety, Joel Dobbin, Itzchak Gilboa, Juan Soto, Bob Brandner, Bill Holmstrom, and the current Reptile House staff. Curators Herndon G. Dowling and F. Wayne King were instrumental in providing a framework for crocodilian science to develop at the Bronx Zoo. Bill McMahan, Louisville Zoological Garden, Louisville, KY provided important species breeding data. We thank Dr. Kent Vliet and R. Andrew Odum, AZA Crocodilian Advisory Group and the staff of the St. Augustine Alligator Farm, and the biologists and scientists who freely and openly shared the fruits of their often hard-gained research and knowledge, in particular, Drs. Myrna E. Watanabe, Carl Gans, Maimon M. Cohen, Jeffrey Lang, Mark Ferguson, and Leslie Garrick; Prof. Huang Chu-Chien; Ted Joanen; and Tony Pooley. We thank Dr. Jennifer Pramuk., Wildlife Conservation Society, for her support. Thanks also go to the new generation of molecular scientists who may yet decide what is a species: Drs. George Amato, Chris Brochu, Lew Densmore. Lastly, and most importantly, we thank the late Dr. Raymond L. Ditmars, who began it all.

Toe Clipping of Anurans for Mark-Recapture Studies: Acceptable if Justified

KIRSTEN M. PARRIS*
and
MICHAEL A. MCCARTHY
School of Botany, University of Melbourne VIC 3010, Australia
** Corresponding author: e-mail: k.parris@unimelb.edu.au*

Individual marking of animals so that they are uniquely identifiable upon recapture is a common practice in ecological field studies (Nietfeld et al. 1994). The return rate observed during a mark-recapture study is a product of the probability of survival (survival rate) and the probability of recapturing an animal that is alive (recapture rate). An ideal marking method will not harm the study organism or change its behavior, and therefore will not affect survival or recapture rates. Toe clipping is a common method of marking anurans, but its use has become controversial (Funk et al. 2005; May 2004) following our study identifying a consistent, negative effect of toe clipping on the return rate of anurans in the wild (McCarthy and Parris 2004).

Phillott et al. (2007) argue that toe clipping is an acceptable method of marking anurans for mark-recapture studies, for three principal reasons. First, because it is unclear whether the observed reduction in the return rate of anurans with increasing numbers of toes clipped is due to changes in survival, changes in recapture rate, or both. Second, because the impacts of alternative marking methods have not been properly assessed; and third, because individual marking of anurans is essential for the conservation management of the group. We would like to respond to some of their points here.

As we state in our earlier papers (McCarthy and Parris 2004; Parris and McCarthy 2001), the negative effect of toe clipping on anuran return rates could be due to an increase in mortality, changes in the behavior of animals leading to a lower recapture rate, or a combination of the two. Phillott et al. (2007), like May (2004) and Funk et al. (2005), focus on the ethical problems associated with reduced survival of toe-clipped animals, implying that behavioral changes following marking are less important. While this distinction is understandable, any impact of toe clipping on anuran behavior also has ethical and scientific consequences. Changes in behavior following toe clipping such as a reduction in calling or foraging activity, or migration from the study area, could have consequences for the fitness of the study animals and the persistence of populations. Furthermore, whether the reduction in return rates is due to the death of the study animals or changes in their behavior, the data arising from a toe-clipping study will be biased. Interestingly, the scientific validity of studies using biased data from toe clipping has received little attention. Some researchers have taken issue with our papers because of subsequent restrictions that could be placed on their use of toe clipping. We are surprised by such reactions, because we had expected that users of a biased research method would want to know the size of the

bias so it could be corrected. Researchers using toe clipping in the future need to ensure that the inherent bias is 1) minimized by careful survey design, and 2) accounted for during data analysis (Parris and McCarthy 2001).

Phillott et al. (2007) propose a number of strategies for minimizing the negative impacts of toe clipping, including removing as few toes as possible and using aseptic handling techniques. We make these same recommendations (Parris and McCarthy 2001), although we propose that care be taken to remove the minimum number of toes from all anurans, not just species that are "heavily reliant on toes". Phillott et al. (2007) suggest that removal of the toe pad only ("toe tipping" rather than toe clipping) may reduce the effects of marking on anurans. While this may be the case, there are no supporting data – in fact, the effect of toe tipping on the return rate of *Hyla labialis* (Lüddecke and Amézquita 1999) is comparable to the effect of toe clipping on the return rate of *Bufo woodhousei* and *Crinia signifera* (Clarke 1972; Lemckert 1996; Williamson and Bull 1996; see McCarthy and Parris (2004), Figs 1 and 2).

It is true that the effects of alternative methods for marking anurans have not been properly assessed in the wild (although Davis and Ovaska (2001) found a 33% lower return rate of salamanders with three toes clipped compared to those implanted with fluorescent elastomer tags). It is likely that other marking methods will affect the recapture and/or survival rates of anurans to some degree, so they, too, must be used with caution. However, the prospect that other methods are just as bad, or worse, than toe clipping does not necessarily make it acceptable. The possible benefits of conducting a mark-recapture study using toe clipping must be weighed objectively against the likely impacts on the study animals, to determine whether toe clipping is justified in a particular circumstance. Phillott et al. (2007) argue that data gained from the individual marking of anurans is essential for their conservation management. For this to be the case, the data must be essential for identifying practical management actions that will improve the viability of a species, and must be of sufficient quality and quantity to achieve this objective. To our knowledge, few mark-recapture studies of anurans meet these criteria, especially studies of threatened species that have small populations. The burden of proof that the value of their research outweighs the harm it may cause lies with researchers who propose a mark-recapture study; the burden of oversight lies with ethics committees.

Parris and McCarthy (2008) have over-simplified the arguments of Phillott et al. (2007) that toe-clipping is an acceptable method of marking anurans. We discussed six points in defending toe-clipping as a marking method:

1. The absence of unequivocal data to quantify the effect of toe-clipping on return rates. Parris and McCarthy (2001) and McCarthy and Parris (2004) used statistical projections, based on five studies with limited details of search effort to evaluate the likelihood of encountering a marked frog and hygiene procedures that may have influenced survival be-

yond current practices (Clarke 1972, Humphries 1979, Lemckert 1996, Williamson and Bull 1996, Lüddecke and Amézquita 1999).

2. The reasons for reduced return rates after toe-clipping. Mortality after an invasive marking procedure is a real and recognized concern. However, failure to encounter an individual after marking can also be due to behavioral changes that may or may not affect the fitness of the study animals.
3. Current hygiene practices minimise the risk of exposure to pathogens. These are less likely to have been or were not considered in the studies which Parris and McCarthy (2001) and McCarthy and Parris (2004) used as data sources.
4. Ethical concerns raised by May (2004) are unsubstantiated, yet have strongly influenced ethics committees, with some recommending the use of anesthetics that are at times inappropriate or have unknown dosage requirements that are likely to pose a greater threat to the well-being of the animals than toe-clipping.
5. Ethics committees have also favoured the use of other marking techniques, such as pit-tagging, over toe-clipping. The majority of these are still invasive, pit-tagging arguably more than toe-clipping, and their effects are at best no further understood than those of toe-clipping. They have certainly not been shown to pose less of a physiological or physical risk to animals.
6. Some field studies require the recognition of individuals, which for many species requires marking techniques such as toe-clipping. We believe such focused studies with measurable outcomes contributing to understanding and management of a species have value that outweighs the potential impacts on the species.

Parris and McCarthy (2008) responded to points 2, 3, 5, and 6. They are largely in agreement with these points although they do not distinguish between the importance of the effects of toe-clipping on mortality versus behavior. They argue that both are equally important because of the potential effect of changes in behavior on population fitness and study bias. Unfortunately there are no data to test whose opinion is correct. Parris and McCarthy (2008) point out that a minimum number of toes should be removed from all anurans; in general we agree but we stand by the intent of our comment that the function and importance of toes should equally be taken into account when toe-clipping. Parris and McCarthy (2008) also suggest that there is evidence that the effect of toe-clipping is no different from that of toe-tipping although the study they cite is confounded by species. In addition, they argue that toe-clipping may be unacceptable even if it is no worse than other invasive methods of marking animals. The point of our comment was that it is always best to use the most practical, least harmful method of marking, and that toe-clipping should be evaluated on that basis, along with other marking methods.

We believe that mark-recapture studies can contribute to the development of conservation management plans for many anurans in a variety of ways. McCarthy and Parris (2008) argue that the risk of toe-clipping is justifiable only if one is answering questions of direct relevance to management applications. Unfortunately, too little is known about many amphibian populations to know in advance what these questions might be. Correctly conducted population studies can be the only means of identifying risk factors. Potential increases in mortality or emigration rates are generally quite small, but can be accounted for in a study and the need for information must be balanced against those risks.

Parris and McCarthy (2008) are surprised that the scientific validity of potentially biased data from studies using toe-clipping has received little attention. We acknowledge that any field research involving the capture and marking of animals may potentially affect return rates through altered survival and/or behavior, so all techniques violate assumptions related to population estimation models, and bias needs to be considered (Phillott et al. 2007). However, in the absence of evidence-based results that prove a lesser effect on return rates of alternative marking techniques, field researchers will continue with toe-clipping as it is known to have small effects that have been quantified for some species. We hope this discussion has shown that toe-clipping and toe-tipping are acceptable techniques if carried out appropriately, that their use needs to be justified, that their effects on a study need to considered when analysing results, and that they will remain in use until alternative techniques are shown to be superior. We reiterate that controlled studies to evaluate the physical, physiological and behavioural effects of invasive marking techniques on a range of frog species are urgently needed.

Phillott et al. (2007) did not primarily aim to address Parris and McCarthy (2001) and McCarthy and Parris (2004) as we believe the weakness of their arguments was adequately discussed in Funk et al. (2003). Our concern is that animal ethics committees and government agencies have banned the use of toe-clipping as a result of these papers, but have done so without evidence that the procedure has a greater effect than the alternative marking methods. Our paper specifically demonstrated the problems with dismissing toe-clipping in favour of other, less understood invasive marking techniques.

Oophagy and Larval Cannibalism without Polyphenism in Tadpoles of the Great Basin Spadefoot (*Spea intermontana*)

SUE FOX
P.O. Box 68, Cedarville, California 96104, USA
e-mail: suefox@hughes.net

Polyphenism associated with cannibalism has been reliably documented in two species of North American spadefoot toads (family Pelobatidae: *Spea bombifrons* and *S. multiplicata*) (Bragg 1956, 1964; Bragg and Bragg 1959; Pfennig 1989; Pomeroy 1981). *Spea* larvae occur as two morphologically distinct phenotypes: 1) carnivores are cannibalistic, have beak-shaped, keratinized mouthparts, and hypertrophied jaw musculature; and 2) omnivores have flat, keratinized mouthparts, and feed primarily on detritus (Bragg 1965; Pfennig 1992; Pomeroy 1981). Pomeroy (1981) noted polymorphism in pools containing *S. multiplicata* 2–4 days after feeding commenced. In *S. multiplicata*, consumption of anostracan shrimps or other tadpoles induces the carnivore morphology and morph determination is reversible based on diet (Pfennig 1990; Pomeroy 1981).

Reports of polyphenism in *Spea intermontana* have been limited to mouthpart characteristics (Acker and Larsen 1979; Black 1973; Orton 1954; Turner 1952). The description provided by Tanner (1939) of the mouthparts of *S. intermontana* collected in Utah has been interpreted as indicative of a carnivore morph (Hall et al. 2002; Pfennig 1992). Subsequent workers have assumed that larvae of *S. intermontana* are potentially morphologically variable (Hall 1993; Hall et al. 1997; Hall et al. 2002). Hall (1998) includes two photographs of the carnivorous and herbivorous morphological types. However, the two types have not been described in detail and there are no reports whether the carnivorous morph is cannibalistic. I report field observations of cannibalism and oophagy by larvae of *S. intermontana* and the lack of polyphenism associated with cannibalism.

Methods.—I conducted this study at permanent, semi-permanent and temporary ponds in Mono County, California, USA (118.965°N, 38.086°W), during the breeding seasons April through June of 1984–1989. Permanent and semi-permanent pools are created by artesian wells. Semi-permanent pools are present year-round, except in drought years. Temporary pools formed from ground water and surface run-off, and were present only during wet years. Study pools varied in size from less than one meter square to several hectares. Additional observations and collections were made from three small pools formed from springs near the south shore of Mono Lake, Mono County, California (119.053°W, 37.940°N).

Tadpoles were observed in the field for 1380 h on 260 days between April 1984 and May 1989. The duration of observations ranged from 3–7 h per day. I identified a tadpole as a cannibal if it was observed eating all or part of a conspecific, while a non-cannibal did not eat a conspecific. For cannibalistic encounters for which an entire sequence was observed I recorded: the length of time it took a cannibal to consume its prey; the number of cannibals feeding on a single tadpole; and the snout–vent length (SVL; tip of the snout to the junction of the posterior body wall and cloaca) and developmental stage (DS, Gosner 1960) of the cannibal(s) and prey.

Tadpoles were collected for morphometric analyses mid-April to mid-June in 1984 through 1987 and during May in 1988 and 1989. Tadpoles were randomly collected with a dip net once a week from the main study pool and less frequently from other pools that contained fewer tadpoles. While phenotypic differences between morphs of *S. bombifrons* and *S. multiplicata* are readily determined by visual inspection (Bragg 1965; Pfennig 1990; Pomeroy 1981; Storz 2004), there were no obvious morphological differences among tadpoles of *S. intermontana* in my study pools. For more detailed morphometric comparisons, cannibals and noncannibals were identified by offering field-collected tadpoles (stages 25–36) at least one pre-feeding stage conspecific for 24 h. Tadpoles were housed individually in 2.4-liter round plastic containers (16.8 cm x 12.5 cm) filled with approximately 1680 ml water to a depth of 8.75 cm. Cannibalism was inferred if a tadpole was missing or its partially consumed remains were present. Tadpoles that did not eat conspecifics were labeled non-cannibals. Cannibals (N = 34) and non-cannibals (N = 36) were preserved for morphometric analysis.

All tadpoles were cold-killed and preserved in 10% formalin. I examined the external morphology of 1089 tadpoles of different sizes and developmental stages. Using dial calipers and a dissecting microscope, three characteristics were measured: SVL, total length (TL; tip of the snout to the tip of the tail), DS, and number of posterior and anterior labial teeth rows (PLT and ALT) using Altig and McDiarmid's (1999) terminology. The criterion for labial tooth row presence was at least three teeth on a tooth ridge. A qualitative description of the keratinized jaw sheaths also was recorded (e.g., serrations on jaw sheaths, thick, thin; see Altig and McDiarmid 1999).

Gut length (GL) and *musculus orbitohyoideus* length (OH) were measured for the 70 experimental tadpoles identified as cannibals and non-cannibals and for 157 tadpoles collected from a single population over the course of their development. These two traits are diagnostic of the carnivore morphotype for *S. multiplicata* (Pfennig 1989; Pomeroy 1981). A dissecting microscope with ocular micrometer was used to measure OH to the nearest 0.1 mm. The relationships of GL and OH to body size were analyzed using analysis of covariance.

I tested whether metamorphs were cannibalized by conspecific larvae by placing metamorphs in the water of ponds 1–2 m from shore. This forced the individual to swim to shore above feeding aggregations of tadpoles. I conducted 35 trials with individual metamorphs in 1984 and 45 metamorphs in 1986.

Results.—Cannibalism was observed on 8 of 260 days of field observations: 6 days in 1984 (April 15–18, 21, 22) and 2 days in 1987 (May 8, 15). A total of 41 occurrences of cannibalism were observed in the 8 days over a period of 27.5 h, in three different ponds. Based on the number of egg clutches recorded in the three ponds and the average number of eggs per clutch (mean = 812, SD = 297), the number of tadpoles present on each day the cannibalism was recorded ranged from 4872 to more than 10,000 tad-

poles (Pond 1 ≥ 10,000, Pond 2 4,872, and Pond 3 5,684).

All cannibalistic encounters occurred in feeding aggregations in the vicinity of a clutch of conspecific eggs that had hatched within the previous two days or were in the process of hatching. Cannibals were in early feeding stages, 25–27, and preyed on tadpoles in stages 20–25. Prey tadpoles with yolk sacs did not struggle while older tadpoles in stages 24–25 lashed their tails, but did not escape. Cannibals seized conspecifics on all body sites, including the head, back, abdomen, and tail. Cannibalistic encounters were initiated by a tadpole butting into another individual with its snout. Butting was a characteristic behavior engaged in by feeding tadpoles. Cannibalistic tadpoles did not pursue their prey if it moved away when butted, nor did they remain in the vicinity of newly hatched tadpoles to selectively hunt and prey on them. Most tadpoles that butted into newly hatched conspecifics did not seize them. These non-cannibals were frequently observed resting alongside or on top of newly hatched tadpoles.

Other tadpoles butted the feeding cannibal and some individuals seized part of the prey. Some individual tadpoles fed on the prey for a few minutes before leaving and being replaced by another tadpole. In 32 instances where the entire cannibalistic encounter from initiation to complete consumption was observed, from 1–7 tadpoles consumed part of a single newly hatched tadpole (mean = 2, SD = 1.5).

Cannibals were behaviorally and morphologically indistinguishable from other tadpoles in the feeding aggregations. However, their cannibalistic feeding behavior was conspicuous because they jerked sharply from side to side as they engulfed their prey. Groups of cannibals feeding on one tadpole tugged in opposing directions and tumbled about in the water, often upside down. In three cases, one individual pulled the prey away from the other tadpoles and rapidly swam away. The other tadpoles pursued a few millimeters before stopping to feed elsewhere.

In 19 timed observations, a cannibal consumed a tadpole in less than 5–2400 sec (mean = 866 sec, SD = 697.7). Large cannibals consumed small prey faster than cannibals that consumed prey close to their size. Some cannibals were the same size (SVL) as their prey, while others were up to 50% larger. The length of time for ten groups of two or more cannibals to completely consume the same prey ranged from 79–1800 sec (mean = 610.6, SD = 554.4).

Cannibalism was not observed experimentally or incidentally on transforming tadpoles, but was recorded on dead and injured tadpoles. In 1985, cattle fed and watered directly in the main study pool. The cows killed some tadpoles and mortally wounded others when they waded in the pond. Dead and injured tadpoles burst open so that their intestines were exposed. Unaffected tadpoles ate the intestines of both dead and live tadpoles as well as other internal organs. The cannibals did not eat the remainder of the tadpoles' bodies (e.g., head, back, tail) until several days later when the carcasses were affected by fungus and algae. The cattle's hooves also created water-filled depressions along the pond's margin. Fluctuations in water levels caused some of the depressions to become separated from the main body of water, trapping tadpoles that died when the water evaporated. When the water level rose again, tadpoles formed feeding aggregations on the dead tadpoles.

Toads appeared to employ a flexible breeding strategy in response to annual hydrologic conditions that appeared to be related to the incidence of oophagy. During dry years (1985, 1986), they were explosive breeders and females deposited their eggs in a period of a few days. In wet years (1984, 1987), they were prolonged breeders and females deposited their eggs over a period of two months. During prolonged breeding seasons, oophagy was observed in all study pools, except in temporary pools in which only one clutch was deposited. In explosive breeding years, few to no feeding stage tadpoles were present that could eat conspecific eggs as there were only a few days of overlap in the time of occurrence of eggs and larvae.

Thirty-eight of 118 egg masses (32%) were completely eaten by conspecifics. Nine of 118 egg masses were destroyed by desiccation (7.6%). Dense aggregations of feeding tadpoles formed on both viable and nonviable clutches of eggs. Nonviable eggs were affected by fungus, and the outer jelly became coated with green algae. Females typically deposited multiple, discrete clumps of eggs. Asynchronous hatching of eggs was recorded in 75.6% of egg clutches (N = 91; range = 1–4 days). Asynchronous development of embryos within clutches provided opportunities for sibling cannibalism as some tadpoles hatched up to four days before their siblings. Sibling cannibalism was observed only once when two Stage 25 tadpoles ate a Stage 20 tadpole. All three tadpoles were from the same discrete clump of eggs.

Female toads appeared to select egg deposition sites away from egg clutches and aggregations of tadpoles (unpubl. data). Due to patterns of egg deposition and oophagy, few situations existed in the field where tadpoles greater than Stage 27 could prey on newly hatched tadpoles. The females' egg laying was not always effective at preventing complete depredation. In 1984, ten clutches of eggs were entirely consumed in less than five days.

Analysis of covariance, with SVL as a covariate, revealed no significant differences in GL or OH length between cannibals (N = 34) and noncannibals (N = 36) for these variables. The use of developmental stage as a covariate in addition to SVL also showed no significant difference between cannibals and noncannibals for either OH ($F = 0.32$; $df = 1, 70$; $p > 0.05$) or GL ($F = 0.79$; $df = 1, 70$; $p > 0.05$). The standardized residuals of OH (mean = 2.68, SD = 8) and GL (mean = 144.3, SD = 113.5) regressed against SVL (mean = 13.8, SD = 8.9) were used to check for bimodality for a subset of tadpoles randomly collected from a single pond (N = 157). The results showed normal curves, which suggest that only one morphotype was present (see Pfennig 1990).

There was a difference in the number of posterior labial teeth rows between cannibals and noncannibals ($\chi^2 = 13.2$, $df = 3$, $p < 0.01$) but not anterior teeth rows ($\chi^2 = 1.5$, $df = 2$, $p > 0.05$). Cannibals had more rows of posterior teeth (mean = 1.85, SD = 1, range = 0–3) than non-cannibals (mean = 0.9, SD = 1.2, range = 0–3).

The number of labial teeth rows varied among tadpoles sampled from the same pool from 1984–1987. Analysis of variance for homogeneity among samples of tadpoles from four different years revealed that the differences in mean number of posterior and anterior labial teeth rows among the years were significant (posterior: $F = 18.4$; $df = 3, 199$; $p < 0.001$; anterior: $F = 7.8$; $df = 3, 199$; $p < 0.001$). There was also a difference in the mean number of posterior labial teeth rows among samples of tadpoles collected from three different pools ($F = 6.5$; $df = 2, 77$; $p < 0.01$), but not for mean number of anterior labial teeth rows ($F = 1.2$; $df = 2, 77$;

$p > 0.05$).

The tadpoles' lower jaw sheaths formed a shallow to steep V-shape, while their upper jaw sheaths were medially rounded. No tadpole (N = 1089) had a jaw sheath with the incised morphology indicative of the carnivore morphs of other *Spea*. The jaw sheaths of tadpoles collected from small pools with little organic matter were characterized by reduced pigmentation that was brown in color rather than the typical black pigment. Sharply serrated jaws were present in 93 of 1089 (8.5%) tadpoles examined, but were not present in any of the known cannibals. The serration might wear away with use of the jaws because it was not observed in any tadpoles greater than Stage 30.

Discussion.—Tadpoles exhibited both opportunistic cannibalism in which the prey does not attempt to evade the predator (e.g., oophagy), and cannibalism, in which conspecifics were attacked, killed, and eaten (Crump 1986). Groups of tadpoles feeding on a single prey did not always involve predaceous cannibalism, because in many cases, the prey was already dead from the initial cannibal's feeding activity.

Cannibalism in this population of *S. intermontana* was not associated with poylphenism. Cannibalistic tadpoles did not appear to require specialized oral morphology because the age classes of their prey were vulnerable and easily eaten. The only morphological trait found to differ between cannibals and non-cannibals was the number of rows of posterior labial teeth, which were greater in cannibals. This trait cannot be considered diagnostic of cannibalism or a history of cannibalism because the number of tooth rows also varied by: pool site; year for the same pool; and developmental stage of the tadpole. Reduced number of labial tooth rows, particularly the anterior rows in *S. multiplicata*, is a characteristic trait of *S. hammondii*, *S. bombifrons*, and *S. multiplicata* carnivore morphs (Bragg and Bragg 1959; Bragg 1965; Pomeroy 1981). However, this is only one trait among a suite of morphological and behavioral characters indicative of polymorphism. Moreover, numerous investigators have reported microgeographic variability in labial tooth rows for other species of *Spea* (Bragg and Hayes 1964; Bragg et al. 1964; Hampton and Volpe 1963; Potthoff and Lynch 1986) as well as for *S. intermontana* (Brown 1989; Hall 1993).

Polyphenism in *S. mulitplicata* and *S. bombifrons* appears to occur because these species inhabit variable environments where discrete trophic morphs may provide a selective advantage. The carnivore develops faster than the omnivore and survives better in rapidly evaporating ephemeral pools, while the omnivore survives better in long-lasting pools (Pomeroy 1981; Pfennig 1990). The heterogeneous environmental conditions that make polymorphism evolutionarily advantageous for other *Spea* species may be missing in this population of *S. intermontana*. Tadpoles in my study area developed in permanent and long-lasting temporary pools and did not appear to experience any selection pressure to escape evaporation. Use of permanent bodies of water, including human-constructed impoundments, has been noted in other populations of *S. intermontana* (Blair 1956; Brown 1989; Morey and Reznik 2004). Desiccation before metamorphosis was not a source of mortality in this study population (unpubl. data). Morey and Reznik (2004) also reported no risk of evaporation for their study population of *S. intermontana*.

Differences in developmental markers between *S. intermontana* and other *Spea* suggest that *S. intermontana* might have evolved in long-lived pools. The eggs of *S. intermontana* took an average of 6.5 days to hatch, with a range of 4–9 days. The eggs of other *Spea* species hatch within an average of 48 h (Black 1973; Bragg 1965; Mayhew 1965; Pomeroy 1981). The minimum time to metamorphosis for *S. intermontana* tadpoles in my study area ranged from 36 days in 1985 to 75 days in 1984. Brown (1989) reported 36 days for *S. intermontana* tadpoles to complete development, Nussbaum et al. (1983) reported that *S. intermontana* larvae metamorphose after one or two months of larval development, and Morey and Reznick (2004) reported a range of 36–79 days. Other species of *Spea* have a minimum time to metamorphosis of 13 days (Black 1973; Pomeroy 1981).

It is likely that under natural field conditions, as well as in the laboratory experiment, cannibalism in this population was too limited in scope to produce any effect on morphology. Fairy shrimp (*Brachinecta mackkini*) were not sympatric with tadpoles of *S. intermontana* at my study sites; the fairy shrimp occupied saline water and could not survive in the fresh water inhabited by the tadpoles. Thus, a dietary mechanism that causes differential morph development in *S. mulitplicata* larvae appears to be lacking in this population of *S. intermontana*. The only other report of cannibalism in larvae of *S. intermontana* did not note any morphological differences among the larvae (Durham 1956).

The lack of evidence for a carnivore morph in *S. intermontana* from my study in Mono County, California, compared to specimens from Washington State and Idaho, might not be unexpected for a species that is widely distributed. It is possible that *S. intermontana* has a latent potential for polyphenism that is more readily expressed in other geographic locations and under different conditions. The mechanism by which this occurs warrants further investigation.

Acknowledgments.—This research was funded in part by the Theodore Roosevelt Memorial Fund of the American Museum of Natural History and a Grant-in-Aid of Research from Sigma Xi.

Spring Peepers and Pitcher Plants: A Case of Commensalism?

RONALD W. RUSSELL

Sarracenia purpurea (Northern Pitcher Plant) is a carnivorous plant found throughout northeastern North America (Schnell 2002). This plant is frequently encountered in nutrient-poor bogs, often associated with *Sphagnum* spp. The water-filled, pitcher-shaped leaves of *S. purpurea* serve as a trap for small invertebrates attracted by extra-floral nectaries near the entrance to the pitcher. Once entry to the pitcher is accomplished, escape is difficult due to downward oriented hairs on the inner surface of the leaf, and captured organisms drown in accumulated rainwater. Nutrients from decomposing invertebrates are absorbed by the plant (Ellison and Gotelli 2001). Capture efficiency of insect prey in Northern Pitcher Plants is low (0.83–0.93%) (Newell and Nastase 1998). A mutualistic relationship is hypothesized to exist between pitcher plants and the inquiline community contained within the pitchers (Bradshaw and Creelman 1984; Ellison and Gotelli 2001). Tiny vertebrates are also known to become entrapped in *Sarracenia* pitchers (Schnell 2002).

There are a number of anecdotal references to amphibian consumption by *Sarracenia* pitchers as well as pitcher use by amphibians in the popular press (The Sentinel 2007). One of the earliest references to *Sarracenia* describes pitchers as insect refugia from amphibian predation (Catesby 1743). Amphibians are known to become entrapped and digested in pitchers (Butler et al. 2006; Schnell 2002), forage for insect prey on pitchers (Jones 1935), and inhabit pitchers (Lim and Ng 1991). In this study, I quantify pitcher use by *Pseudacris crucifer* (Northern Spring Peeper) and elucidate the nature of the frog-pitcher plant interaction.

Twelve adult Northern Spring Peepers (8 females, 4 males) were collected from the field in early May 2004 and placed in a 90-liter glass terrarium extensively planted with *Sphagnum* sp. and four Northern Pitcher Plants with 5–11 pitchers per plant. Pitcher plant density in the laboratory was similar to plant densities observed in the field and peepers had access to non-dessicating roosting sites within the *Sphagnum* mat. All spring peepers were reproductive and ranged in SVL from 18–26 mm. Spring peeper density in the laboratory was much greater than observed in the field. Amphibians were fed wingless fruit flies and juvenile crickets. The artificial habitat was observed at least 3 days per week from May–September for 15 minutes per day. Fruit flies were attracted to extra-floral nectaries on pitchers and spring peepers were frequently observed (at least once per observation period) climbing pitchers to consume these insects. Peepers were routinely observed inside *S. purpurea* pitchers during the day, but were never observed feeding while inside pitchers. Suitably sized pitchers of all plants were occupied and no territorial behavior was observed. Occupancy rates were typically less than 5% (0, 1, or 2 peepers observed in pitchers). Only pitchers large enough to admit peepers were used to

estimate occupancy. The entrance to the smallest pitchers was too small to admit adult frogs, but could potentially accommodate recently metamorphosed spring peepers. This microcosm was maintained for six months, with no amphibian losses resulting from entrapment in pitchers.

Sarracenia purpurea plants located on a coastal barren near Halifax, Nova Scotia, Canada (44°33.246'°N, 63°31.396'W) were surveyed for the presence of spring peepers. In 2004, 163 pitchers were observed and 306 in 2005. Density of Northern Pitcher Plants based on ten random 1 m quadrats was 8.5 ± 4.4 plants/m^2. Quadrats were selected by overlaying a sketch of the study area using approximate distances with a grid, randomly numbering the squares of this grid, then selecting ten squares by a random number generator for density estimates. Spring peeper surveys were conducted over three consecutive days during late May in both years in a large bog dominated by *Sphagnum* sp., *Eriophorum* sp., and *Sarracenia purpurea* where plants grew on a nearly continuous mat of *Sphagnum.* Observations were limited to a relatively short period at the peak of the spring peeper breeding season since these amphibians disperse back into the forest following reproduction. Additionally, in late May 2005, 50 pitchers were randomly collected from this site, dissected by longitudinal incision with a scalpel in the laboratory, and examined for the presence of amphibian remains. Five pitchers of sufficient size were collected from ten quadrats, randomly selected as described above.

There were no peepers observed in *Sarracenia* pitchers in 2004, however in 2005, four spring peepers were observed in pitchers during daylight. This corresponds to an incidence of 1.3% of pitchers occupied. When a pitcher was determined to be occupied by a spring peeper, it was marked with a ring of jute twine. Marked pitchers were inspected the following day and it was observed that none was occupied on consecutive days, indicating that amphibians had moved prior to the second survey. Frogs were not trapped within the previously occupied pitchers. Night surveys of 12 wetlands on this same coastal barrens from 2002 to 2006 (at least 8 surveys per year) revealed a large and active spring peeper population based on call surveys. Peepers were occasionally observed calling from pitchers at night and none of the 50 dissected pitchers contained identifiable amphibian remains. Complete digestion for trapped amphibians in *S. purpurea* pitchers requires at least 10 days (Butler et al. 2006). The sample of dissected pitchers was probably too small to detect amphibian remains with 1% or less.

The combination of laboratory behavior and field observations indicate that spring peepers occasionally use *Sarracenia* pitchers. Peepers forage for small insects attracted by extra-floral nectaries on the pitcher, intercepting invertebrates that might otherwise become plant food. There is no obvious advantage to the plant from this interaction, thus no mutualistic association, as observed with the pitcher-inquiline community, which assists in decomposition and release of nutrients to the plant. By intercepting nutrition that would normally be routed to the plant and inquiline community, spring peepers may function as parasites; however, only a small fraction of insects attracted to the extra-floral nectaries become entrapped in the pitcher (Newell and Nastase 1998). Parasitism is a minor interaction because of the low incidence of peepers in pitchers. Peepers may function as commensals by harvesting insects attracted to the pitcher.

Spring peepers forage for insect prey mostly during the day (Oplinger 1967), thus exposing these amphibians to potentially desiccating conditions. Peepers avoid desiccation during dry conditions by moving under debris (Wright and Wright 1949). The moist environment of the *Sarracenia* pitcher provides an ideal refuge from desiccation for amphibians. While refuge in the pitcher may appear to be neutral to the plant, the amphibian partially occludes the entrance to the digestion chamber by taking residence in the pitcher, which may affect pitcher trapping ability. Additionally, the frog is in an ideal position to consume trapped insects. This interaction clearly does not benefit the plant. Use of pitchers as a refuge was a rare event (1.3%) at the study site therefore this was not an important intertaxa interaction at this particular location. The importance of this interaction may increase where pitcher plants are less abundant. While use of Northern Pitcher Plants by spring peepers is not beneficial to the plant, it is a rare event. Consumption of amphibians by pitcher plants is an equally rare event (Butler et al. 2006) which could compensate plants for nutrition usurped by spring peepers.

Acknowledgments.—Funding was provided by a Discovery Grant from the Natural Sciences and Engineering Research Council of Canada. Permits were obtained from the Nova Scotia Department of Natural Resources and the local Animal Care Committee. I thank A. M. Ellison and an anonymous reviewer for constructive comments on this manuscript.

In 1937 Howard K. Gloyd led a herpetological expedition to southern Arizona (Gloyd 1937). Film records show a body-flipping reaction, termed "plays dead," of a Regal Horned Lizard (*Phrynosoma solare*) to prodding with a thin stick and subsequent human handling. An adult lizard repeatedly flipped itself onto its back, nine times within 25 s (immediately righted by Gloyd's hand after each flip). We found only one subsequent mention of the behavior in *P. solare*, without functional explanation (Parker 1971).

Death feigning, letisimulation, or tonic immobility, has been considered an antipredator response across invertebrate and vertebrate taxa without clear identification of its adaptive significance (Carpenter and Ferguson 1977; Greene 1994; Honma et al. 2006; Ruxton 2006; Ruxton et al. 2004), although in some predatory fish the use of death feigning appears to be clearly adaptive during aggressive mimicry (Tobler 2005). Many hypotheses offered to explain immobility responses of prey tacitly assume that prey manipulate predators by sending false information that they are dead and that this information interrupts prey-subjugation behaviors, thus providing opportunities for prey escape (Honma et al. 2006; Ruxton 2006). Honma et al. (2006) proposed that an inducible death-feigning response of a pygmy grasshopper (*Criotettix japonicus*) is a specific antipredator response against a gape-limited anuran predator to avoid being swallowed. The grasshopper's characteristic rigid posture, with body parts physically extended, interferes with prey manipulation and does not mimic death, but directly enhances prey survival.

In the case of *P. solare*, it is difficult to identify an evolutionarily adaptive advantage to body-flipping and re-flipping, to upside-down, by an immobile, death-feigning, animal. This leaves the behavior lacking a clear biological explanation. Our study attempts to place body-flipping and immobility behavior by *P. solare* in the context of adaptive antipredator behaviors that are effective resistance against specific predators that rely on jaw capture of prey which they ingest whole, such as a non-venomous snake.

We report several additional encounters (rare) of body-flipping behavior in *P. solare* in response to human handling. We then describe field trials aimed at elicitation of the body-flipping and immobility response or alternative responses (such as running flight) in specific predator-context encounters involving two snakes, one non-venomous (*Masticophis flagellum*) and one venomous (*Crotalus atrox*). The two snakes present the lizards with two different threats based on their prey-subjugation strategies (Endler 1991; Sherbrooke 2008), 1) *M. flagellum*: search/wait, identify, rapidly pursue, physically jaw-capture, subjugate, and ingest, and 2) *C. atrox*: wait, identify, envenomate (strike), track, and ingest carcass. We use our observations to propose that the lizards distinguish between two categories of predator threat, the two snakes, and respond to each with distinctive antipredator behaviors (flipping or running) that appear appropriate for selectively enhancing survival in response to each predator's subjugation skills. We also use the differences in responses of *P. solare* to the two snakes to propose a hypothesis for the previously unexplained body-flipping and immobility behavior, noting the predator contexts in which it is employed and not employed, and we discuss aspects of body-flipping and immobility that may function as antipredation defenses with *M. flagellum*.

Methods

Carpenter and Ferguson (1977) reviewed literature reports and numerically catalogued lizard behaviors (termed "act systems") involving body inversion (act system #26, turn over) and letisimulation (act system #150) in various lineages of lepidosaurians. Similarly, Greene (1994) enumerated several categories of antipredator behaviors (#3, catalepsy, letisimulation, death feigning, tonic immobility; #22, invert body). It is difficult to unequivocally assign our observations to a particular category due to the paucity of examples, diversity of descriptions, and frequent lack of meaningful context for the reported behaviors. We simply use descriptive terms, body-flip and immobility behavior. In a body-flip followed by immobility a lizard rapidly raises one side (by extending its legs on that side) to effect a role over along its nose-to-vent axis, landing upside down where it remains motionless (see Figs. 1 and 2).

Following an observation of repeated body-flipping and immobility of a captive *P. solare* in response to human handling (Fig. 1, A–C; 30 June 2006), we reviewed our field notes and summarized additional records of this behavior.

We then studied the behavioral responses of adult *P. solare* during field trials utilizing a known ophidian predator of *P. solare*, the Coachwhip (*M. flagellum*) (Kauffeld 1957), that also preys on other similarly-armored horned lizards (Sherbrooke 1981). The individual *M. flagellum* (SVL 128 cm, tail length [TL] 47 cm; mass 787 g) utilized had previously been observed to capture and eat a *P. solare* (SVL 88 mm, TL 48 mm; mass 36.4 g) on the study area (May, unpubl. data). Our trials involved four *P. solare* fitted with radio-transmitters (Holohil PD-2; approximately 3 g), which were relocated in the field, and six lizards encountered in situ while traversing the study area. Fourteen trials, involving 52 encounters (presentations), occurred between 26 August and 2 September 2006 (Table 1): 0930–1200 h MST (12), and 1730–1900 h MST (2). The study area is immediately adjacent, on the west and northwest sides, to a small volcanic hill in the Altar Valley, Pima Co., Arizona (32°02'11.5"N, 111°23'46.6"W, datum WGS 384).

During trial encounters, the *M. flagellum* was restrained in gloved hands at mid-body, allowing the anterior third or more to move freely as it was held to the ground approximately 1 m from the lizards. It was then allowed/encouraged to approach and contact each lizard (Fig. 2, A). During each trial, an attempt was made to expose the lizard four times to the snake. Contact by the snake

TABLE 1. Summary of behaviors exhibited by ten Regal Horned Lizards (*Phrynosoma solare*) in response to approach of a Coachwhip (*Masticophis flagellum*) in 14 trials involving 52 staged encounters (usually 4/trial). For runs, specific encounter numbers (1–4) are identified. Encounter data are summarized, including number of tilts/trial and the distance (estimated ranges in dm; distance data not complete for lizards #3 26 August, and # 7) of the snake when initiated, occurrence of horn raising by the lizard, and number of encounters in which the snake effected tactile contact, or not, with the lizard. In addition, for encounters of each trial, the mean time and range of the lizard remaining in a flipped position for encounters of each trial are presented.

Lizard # Trial — Date	Sex	SVL (mm)	Lizard body-flip encounters /trial	Lizard run encounters /trial, (#)	Tilt #/s distance (range, dm)	Horns raised (+ / –)	Snake contact (+ / –)	Flip mean/range (s)

(present +, or absent –) prior to a lizard response (body-flip or run) was noted. Following a lizard response, the snake was withdrawn and hidden from view behind the experimenter. A subsequent encounter was initiated within about 1 min of the lizard's righting itself. Reactions of the lizards were noted: distance at which body tilting (dorso-ventral flattening of the abdomen while raising one side and lowering the opposite side, as in "dorsal shield;" Sherbrooke 2008) toward the snake occurred, body-flipping, time lizards spent resting on dorsum following flipping before self-righting, eyelids (opened or closed), eyelid bulging (present or absent), horns raised (executed +, or not – ; Sherbrooke 1987), color change (effected or not, and resulting color), running escape (if employed, distance). For each trial, a range of the four encounters is given for the distance at which the lizard began exhibiting tilt behavior (except in trials with fewer encounters, Table 1).

On 14 September 2006 we studied, in a similar fashion (Table 2) and at the same field site noted above, the behavioral responses of adult *P. solare* to a known venomous ophidian predator, the Western Diamond-backed Rattlesnake (*C. atrox*) (Vorhies 1948), which also preys on other horned lizards (Sherbrooke 2003, unpubl. data). The snake was collected west of the Tucson Mountains, Avra Valley, Pima Co. Tucson, Arizona (32°11'09.5"N, 111°05'58.9"W). The snake (SVL 82 cm, TL 8 cm; mass 385 g) was placed in a 46 cm long clear plastic tube of 3.5 cm diameter. The snake's head and fore-body extended 15 cm from one end of the tube (Fig. 2C), and the tail extended from the opposite end. The apparatus, with snake, was hand held at the tube base where the posterior extending portion of the snake was duct-taped to the tube rim to ensure a grip of adherence to the snake's body scales without undue constriction, thus preventing forward movement in the tube. The tubed snake, safely and not aggressively restricted in its movements, was held with its head extended during encounters.

Trial encounters were conducted between 0900–1100 h MST, with five lizards (including the four radiotagged lizards) having had previous encounters with *M. flagellum*. The other three lizards (#s 1, 2, 7) had no previous experimental contact with snakes. The radiotagged lizards were located and tested where found in the field. The other four lizards had previously been captured and briefly maintained (3–8 days) in outdoor enclosures (fed and watered) before release back at their field capture sites, where they were subjected to our trial encounters.

The eight lizards were exposed to *C. atrox* in a total of 24 encounters (presentations), which varied between two and six depending on the outcome of encounters. Similar to the *Masticophis* encounters, the rattlesnake's fore-body was placed on the ground near the lizard and moved toward the lizard until it was within attack distance. The anterior portion of the snake extending from the tube moved freely as the snake explored its surroundings. Lizards that ran were followed and the snake was again presented to the lizard, usually within a minute of it having stopped.

RESULTS

Body-flip responses to human stimuli.—Incidental to other studies that involved capture of hundreds of *P. solare* over the years

TABLE 2. Summary of running (including distances run in m) and body-flipping behaviors exhibited by eight Regal Horned Lizards (*Phrynosoma solare*) in response to 24 encounters with a Western Diamond-backed Rattlesnake (*Crotalus atrox*). The number of encounters of a trial in which body tilting, horn raising, and snake contact with the lizard occurred are noted.

Lizard #	Sex	SVL (mm)	# encounters	Lizard run encounters #, distance (m)	Lizard body-flip encounters #	Tilt #	Horns raised (+)	Snake contact (+)
1	M	89	6	4 (1–2)	0	0	0	2
2	M	93	3	0	0	3	3	3
3	F	96	2	2 (0.5)	0	0	0	0
4	F	100	2	2 (1–2)	0	0	0	0

8	M	88	4	0	4	3	0	2
totals			24	15	4	8	3	7

1976–2006 in Pima Co., Arizona, we observed and recorded eight instances of body flipping and immobility (5 females, 3 males; SVLs 29, 48, 62, 69, 91 mm, and 61, 91, 96 mm, respectively) in response to human prodding or handling during the months of April (1), June (4), July (2), and September (1); we estimate this was < 1% of captures. All eight lizards repeated flipping of the body in response to being righted (6, 9, 11, and 10–15 times; and four lizards flipped numerous uncounted times), thus repeatedly exposing the lizard's solid-white or white with small black/gray-dots ventral surface, with all legs extended to the sides, tail down on substratum, and the lizard lying on its back (Fig. 1, A–C). Each body flip was accomplished quickly enough so that it was difficult for the human eye/brain to follow the motion (although captured on film, 1/250 s exposure). Lizards remained on their backs for several seconds to many minutes before righting themselves between flips. Four of these lizards had been previously or were subsequently captured without exhibiting body-flipping behavior.

Predator-prey trial encounters with *Phrynosoma solare* and *Masticophis flagellum*.—Of 52 total encounters with *M. flagellum*, 48 (92%) resulted in the lizard doing a body-flip (Fig. 2, A, B) and four (8%) resulted in a run, without a body-flip. All lizards that exhibited a body-flip initially showed some form of body tilting toward the approaching snake, as did three of the four lizards that ran. The snake's distance from the lizard at which this reaction by the lizard was initiated was usually 20–50 cm (Table 1). The raising of horns and lowering of rostral nose/chin areas was seen in approximately half of the encounters (24 of 52; Table 1), but not in the lizards that ran. In the raising of horns response, individual lizards showed variation within a trial from encounter to encounter (Table 1), and individual lizards changed the predominance of their reactions (+ or –) from one trial to another (lizard #s 2–4; Table 1). The snake made contact with the lizard in 43 of 52 encounters; of the nine encounters in which contact by the snake was absent, four resulted in lizard runs and five in body-flips. Most lizard body-flips (90%) were associated with a tactile stimulus by the snake. No runs were initiated by contact with the snake. Of 46 body-flips for which the duration of time spent on its back before the lizard righted itself was recorded, the mean time spent inverted was 34 s, range 2–123 s; encounter data were only recorded twice for lizard # 4 (2 September) and lizard # 6, and were only recorded three times for lizards # 7 and # 10. All body inversions (lateral rollovers) to return to standing posture were executed in a slower and more deliberate fashion than the original instantaneous body-flip, but still quickly. These were accomplished in the visual absence of the snake, in the presence of the experimenter, and with the lizard's eyelids open. In four cases of body-flipping behavior, the time the lizard remained inverted during a flip was not recorded (Table 1). Four encounters in two trials were omitted due to running escapes (lizard # 1 ran down a rodent hole on 26 August, and lizard # 4 ran 41 m, terminating the encounter trials, on 2 September); this reduced total encounters from 56 to 52 (Table 1). With the four radiotagged lizards (#s 1–4), trials of four encounters each were repeated twice, a week apart; all are reported together (Table 1).

During the trial encounters, no lizard exhibited eyelid swelling, engorging the circumorbital sinuses with blood (associated with canid defense; Middendorf and Sherbrooke 1992). In addition, lizards were noted to have their eyelids closed during body-flipping and initial resting upside down, but then to open their eyelids prior to rolling back onto their ventral side. And, frequently, but not always, lizards appeared to exhibit a change in color, usually becoming lighter and more yellow during the predator encounters. No tongue extrusions, that might have enhanced taste or vomeronasal exploration, were seen before or after body-flipping. The snake did not bite any lizard during the trials.

Predator-prey trial encounters with *Phrynosoma solare* and *Crotalus atrox*.—In responses during the 24 encounters with *C. atrox*, the eight lizards ran 15 times (62%), body-flipped four times (17%), and failed to respond five times (21%). Five lizards (#s 3–7; 63%) executed runs in all of their encounters (11), and one lizard (12.5%) ran in four of six encounters. Two lizards (25%) failed to run in any encounter; one was previously exposed to a snake (# 8) and one was not (# 2), and one was radiotagged and one was not. Only one lizard (12.5%) executed body-flips in all four of its encounters. In contrast to other lizards, this radiotagged lizard was found in heavy grass cover under a shrub. Time spent inverted was recorded for two encounters (103 s, 71 s). No changes in lizard color were noted.

Of the three lizards that executed body tilting, one ran, and one raised horns. Body contact by the snake was made with three lizards in non-running encounters. One lizard (#2) was struck and fatally envenomated by the rattlesnake during its third encounter (Sherbrooke and May 2008).

Comparison of *Phrynosoma solare* responses to two snake predators.—Some of the responses of *P. solare* to *M. flagellum* and to *C. atrox* appear to be distinct, in spite of the fact that slightly different designs of the two snake trials do not always provide directly comparative sets of data (Tables 1 and 2; see Discussion). These differences in responses of lizards are seen in the predominance of body-flipping/immobility (48 of 52; 92%) over running (4 of 52; 8%) responses to *M. flagellum* encounters and in the predominance of running (15 of 24; 62%) over body-flipping/immobility (4 of 24; 17%) responses to *C. atrox* encounters (no response, 5 of 24; 21%). Considering only the first encounter response of each lizard (omitting non-responses to *C. atrox*) to the two predator threats (to *M. flagellum* 9 body-flips, 1 run; to *C. atrox* 1 body flip, 6 runs), the lizards' reactions again suggest that *M. flagellum* is more likely to elicit body-flipping than *C. atrox*, which is more likely to elicit running that *M. flagellum*. Also, there appear to be differences in other responses of *P. solare* during each encounter with *M. flagellum* and *C. atrox* (Tables 1 and 2).

Discussion

The differences in defensive body-flipping and running escape reactions exhibited by *P. solare* to *M. flagellum* and *C. atrox* appear to be clear, with some possible errors in animal judgment (potentially influenced in one case with *C. atrox* by obscuring vegetation); *P. solare* tends to body-flip to *M. flagellum* and run from *C. atrox*. The other defense responses (Tables 1 and 2; tilt and horns raised) also suggest a greater tendency to run from *C. atrox*, and stand in place to *M. flagellum*. These data suggest that *P. solare* are able to differentiate between these two predatory snakes, as are *P. cornutum* (Sherbrooke 2008). Similarly, female skinks *Mabuya longicaudata* at their nests have been shown to respond with flight from a lizard-eating snake *Elaphe carinata*, and with nest defense against an intruding snake that is an egg-predator, *Oligodon formosanus* (Huang 2006).

Statistical tests were not run on comparisons of the body-flip versus run responses of *P. solare* to *M. flagellum* and *C. atrox* (first responses 9:1 and 1:6, respectively) due to a number of issues, including low number of experimental animals, involvement of some lizards in more than one encounter or trial, differences in pretrial treatment of lizards (radiotagged or not, field encountered or not), differences in methods of restraining snakes, and diversity of conditions at individual field sites. Nevertheless, we feel that the distinctly different responses of the lizards to the two forms of predatory snakes represent real differences in categorization of predators by the lizards during the execution of antipredator tactics exhibited in body-flipping and immobility, and in running flight. Supporting this view, we note that similar and statistically supported response differences were seen under controlled trials in non-field conditions with the same two predatory snakes and *P. cornutum* (Sherbrooke 2008).

The ten rare instances of body-flipping and immobility behavior in response to human handling (< 1%; versus 92 % to *M. flagellum*) that we recorded may be cases of prey error in categorization of predator threat. These responses to humans might be similar to blood squirting at humans in *P. solare*, which occurs in only 4.6% of encounters (Parker 1971), whereas with dogs it occurs in 60% of encounters (Sherbrooke and Middendorf 2001); in *P. cornutum* it occurs in 5.9% of human encounters, 70–100% of

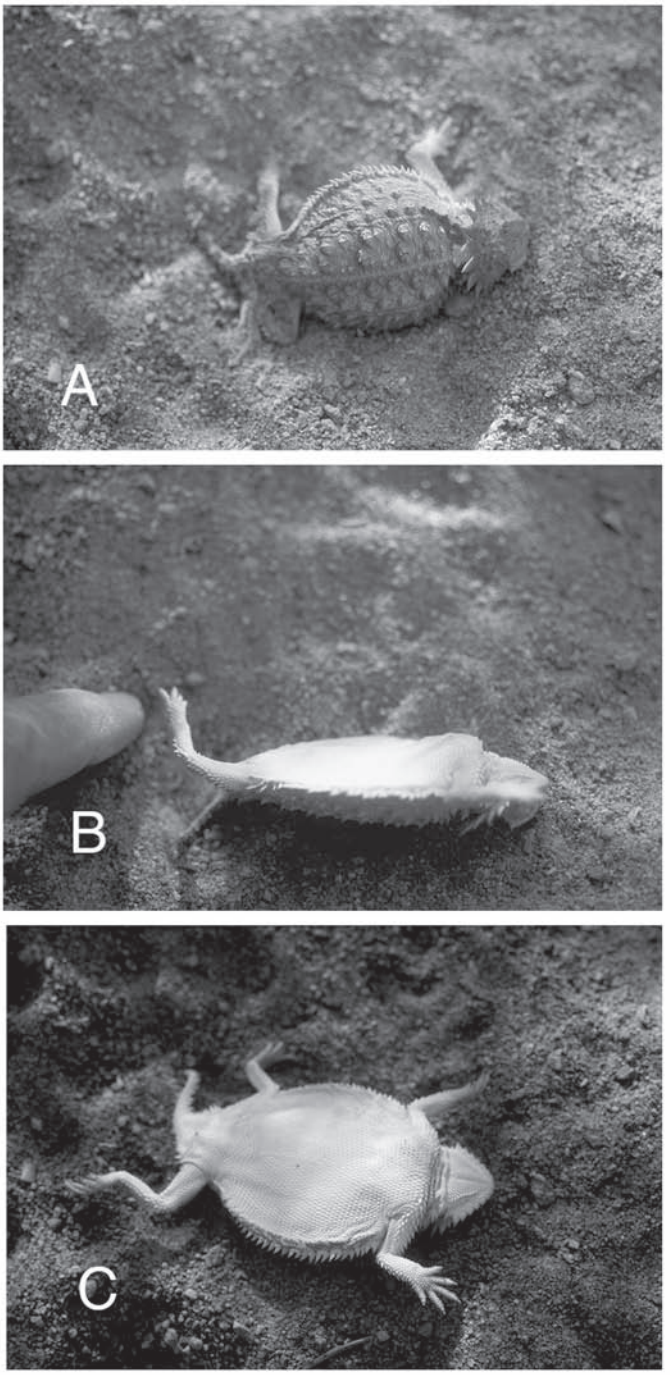

Fig. 1. Adult female (SVL 69 mm) Regal Horned Lizard (*Phrynosoma solare*) exhibiting body-flipping behaviors on 30 June 2006 in response to human handling and righting of body orientation. A) initial upward-thrust of one side in body-flipping. B) mid-flip position (immediately following tactile stimulation by a human finger, left); note closed eyelids. C) inverted posture held following flip, illustrating wide and white ventral surface (not inflated), spread legs, and tail depressed toward substratum. Eyelids were closed.

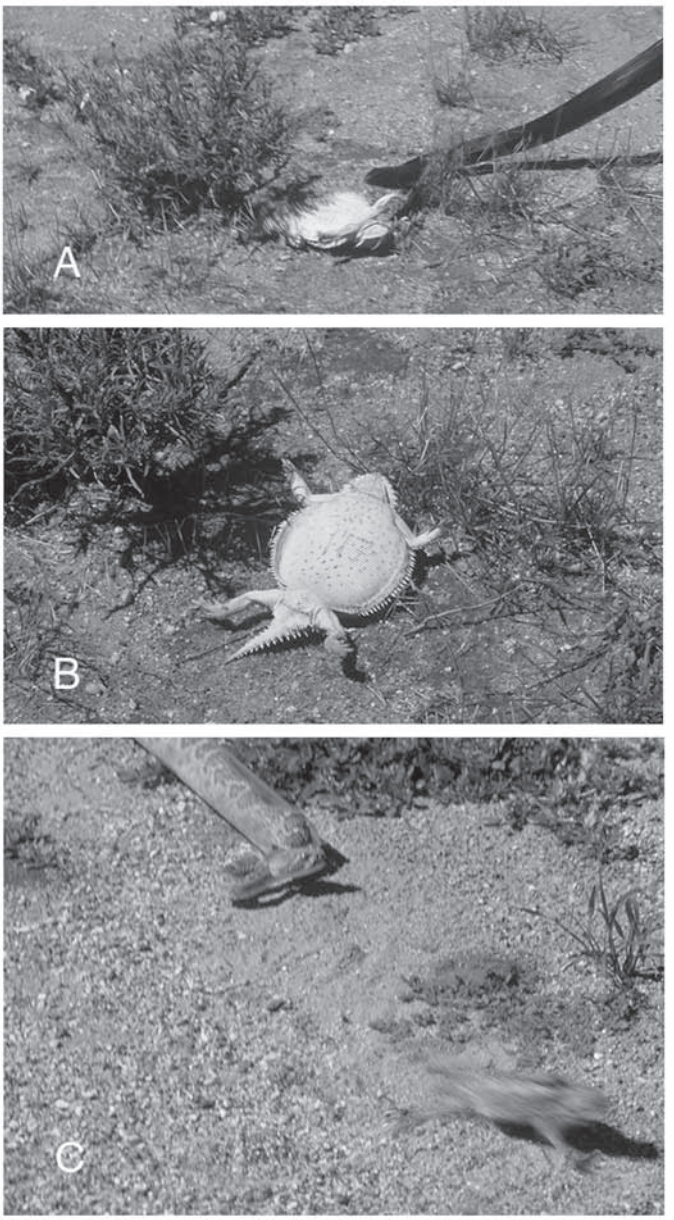

FIG. 2. Responses of adult Regal Horned Lizards (*Phrynosoma solare*) to presentation of encounters with ophidian predators. A) body-flip response to an approaching Coachwhip (*Masticophis flagellum*). B) continued holding of a body-flip response to a *M. flagellum* following retraction and hiding of the snake. C) running response (lower right) to a tubed Western Diamond-backed Rattlesnake (*Crotalus atrox*) (upper left/center).

dog encounters, and 75% of encounters with a native canid (Sherbrooke and Middendorf 2001, 2004). Assuming humans were not a selective force in the evolution of blood squirting (nor in the evolution of body-flipping/immobility behavior in *P. solare*), these significant differences in frequency of horned lizards employing antipredator defenses at humans versus at predators suggest that humans present confounding stimuli that may sometimes erroneously elicit defensive behaviors evolved as defenses against other categories of organisms.

Ingestion of horned lizards by gape-limited predators such as snakes involves significant risk of death to the predator (Holte and Houck 2000; Sherbrooke 1981, 2003; Vorhies 1948). Because of this, features of the *P. solare* body-flip and immobility display may inhibit the likelihood of further attack, depending on the relative size of the snake and the lizard, the experience of the snake, and the snake's level of hunger (Aubret et al. 2007). And, if a snake initiates an attack, the flipped and immobile lizard is in a position for maintaining a stance that maximizes the effectiveness of its physical defenses against such a predator. Rattlesnakes possess similar size-related ingestion limitations as do whipsnakes, but envenomation may reduce some features of resistance to capture and ingestion, such as leg rigidity, but not others, such as horn erection (Sherbrooke and May 2008). A body-flip and immobile response offers little defense against envenomation by a rattlesnake, but a running response distances the lizard from a strike by this predator that does not rapidly pursue fleeing prey.

Phrynosoma solare responses to *M. flagellum* were initiated at a distance of 5–70 cm, suggesting a visual identification of the predator as a precursor to subsequent reactions. Tilting was the most common response (98%). This was followed by body-flipping (92%) and horn raising (54%). We suggest that following visual identification of predator type (as non-venomous rather than venomous; breadth and characteristics of these predator categories have not yet been determined), the lizard adjusts its body defensively with a tilting of its dorsal surface toward the predator, with a raising of the horns in many cases, and then, or even before these reactions, it executes a body-flip.

Once body-flipping behavior has instantaneously inverted a *P. solare*, still located at the site of its encounter with a *M. flagellum*, its appearance has been visually altered. This may startle (Edmund 1974; Ruxton et al. 2004) a non-venomous snake enough to prevent an immediate jaw-grasping attack. During body-flipping the lizard's cryptically-colored and disruptively-patterned dorsal surface (visually fragmented) is replaced by a nearly pure white (sometimes with small gray spots; Fig. 2, B) ventral surface. This surface is broadly oval with a row of lateral fringe scales (jagged in appearance) along each side of the abdomen, four laterally-splayed limbs, and an extended tail. This suddenly appearing new vision may advertise to the snake that its potential prey possesses a broad dimension and extended sharp structures, which present potential difficulties for ingestion (Inbar and Lev-Yadun 2005; Speed and Ruxton 2005). The wide-taxonomic occurrence of uniformly-white ventral surfaces in iguanid lizards suggests that this character is plesiomorphic in the clade. Therefore the uniform-white color of ventral surfaces exposed during body-flip/immobility displays of *P. solare* may have evolved as an exaptation.

If body-flip and immobility displays do not successfully thwart subjugation and consumption by a relatively large *M. flagellum*, it may be unlikely that an attempted running escape would enhance survival. Limb length is short and sprint speed is low in *Phrynosoma* (Bonine and Garland 1999; Pianka and Parker 1975), virtually assuring capture by a pursuing *M. flagellum*. Fleeing prey often elicit chase and capture responses by predators (Cyr 1972), and running horned lizards 1) may not easily visually monitor the movements of a pursuing snake, 2) may provide a horizontally-flattened target for the vertically-grasping jaws of whipsnakes (Sherbrooke 2008), and 3) may be unable to display their morphological features that are threats to whole-prey ingestion.

The best defense of a *P. solare* against a *M. flagellum* appears to be remaining stationary (flipped and immobile), thus visually in-
